What pleased the patient most was the immediate and entire disappearance of her dyspepsia, and she is now well and strong.

REPORT ON PROGRESS IN THERAPEUTICS.¹

BY FRANCIS H. WILLIAMS, M. D.

OIL OF WINTERGREEN AS AN EFFICIENT SALICYLATE IN ACUTE RHEUMATISM.

DR. KINNICUTT² gives a favorable account of the use of this drug in seventeen cases of acute rheumatism.

It is an essential oil, and contains ninety per cent. of the methyl ether of salicylic acid, and has marked antiseptic properties. It may be mixed in all proportions with alcohol and ether, and is slightly soluble in water; it may be given on sugar or in capsules, or shaken with two ounces of water in doses of fifteen minims every two hours. Absorption is rapid, and it is excreted mainly by the kidneys, and rapidly.

The occasional toxic effects of the acid were not observed; ringing in the ears was of infrequent occurrence; in only one case was the slightest gastric dis-

¹ Concluded from page 278.

² Medical Record, November 4, 1882.

turbance excited, and that consisted of a single rejection of the medicine.

As with other salicylates, the dose should be frequently repeated. To avoid relapses it should not be given up too early, but continued in diminished doses throughout convalescence.

Four cases of severe acute rheumatism are reported by Dr. Gottheil;¹ the success was moderate. From five to ten drops were given three or four times a day. In all of the cases the swelling, pain, and local heat rapidly diminished, and the patients were soon convalescent. A certain amount of disability was left, to relieve which it was necessary to have recourse to friction, massage, etc.

Dr. Edward Henderson² has used salicylate of soda in acute orchitis complicating gonorrhœa. He recommends its use only when the temperature is increased and in large doses, twenty grains hourly for at least three doses, and continued later at longer intervals.

THE GERMICIDE VALUE OF CERTAIN THERAPEUTIC AGENTS.

Dr. Sternberg³ has attempted to ascertain the exact value as germicides of some of the agents most frequently employed in medical and surgical practice. The importance of this subject and the care with which the experiments have been done give them unusual interest.

"To test the germicide power of a chemical reagent living bacteria were subjected to its action in a known proportion for a given time, and were subsequently used to inoculate sterilized bouillon. Failure to multiply in this fluid when exposed for twenty-four hours or more to a temperature of 100° F. was considered evidence that reproductive power — vitality — had been destroyed by the reagent used. On the other hand, failure to disinfect, that is, to destroy the vitality of the bacterial organisms used as a test, was shown by the 'breaking down' of the culture fluid.

"The micro-organisms which were used to test the germicide power of the reagents named were obtained from the following sources:—

"(1.) A micrococcus from gonorrhœal pus.

"(2.) A micrococcus from pus obtained from an acute abscess — whitlow — at the moment it was opened by a deep incision.

"(3.) A pathogenic micrococcus having distinct morphological characters obtained from the blood of a septic rabbit.

"(4.) Bacterium termo and other bacterial organisms — micrococci and bacilli — from "broken-down" beef tea which had been exposed to the air.

"In the following table, which is arranged according to the germicide value of the agents named, all experiments are given in which the micrococcus from pus was used as a test:—

EFFICIENT IN THE PROPORTION OF

Mercuric bichloride, 0.005 per cent., one part in	20,000
Potassium permanganate, 0.12 per cent., one part in	833
Iodine, 0.2 per cent., one part in	500
Cresote, 0.5 per cent., one part in	200
Sulphuric acid, 0.5 per cent., one part in	200
Carbolic acid, 1 per cent., one part in	100
Hydrochloric acid, 1 per cent., one part in	100
Zinc chloride, 4 per cent., one part in	50
Tinct. ferri chloridi, 4 per cent., one part in	25
Salicylic acid dissolved by bicarbonate of soda, one part in	25
Caustic potash, 10 per cent., one part in	10
Citric acid, 12 per cent., one part in	8
Chloral hydrate, 20 per cent., one part in	6

¹ Medical Record, September 8, 1883.

² Lancet, December 16, 1882, page 1027.

³ American Journal of Medical Sciences, April, 1883.

"The following reagents, as far as the experiments go, are not shown to have any germicide value, namely:—

Fowler's solution failed in the proportion of	40 per cent.
Sodium hyposulphite failed in the proportion of	32 per cent.
Sodium sulphite (ex-leucata) failed in the proportion of	10 per cent.
Ferric sulphate, saturated solution, failed in the proportion of	16 per cent.
Potassium iodide failed in the proportion of	8 per cent.
Liq. sticti chloridi failed in the proportion of	8 per cent.
Boracic acid, saturated solution, failed in the proportion of	4 per cent.
Zinc sulphate failed in the proportion of	20 per cent.
Sodium borate, saturated solution, failed in the proportion of	4 per cent.
Sodium salicylate failed in the proportion of	4 per cent.

"Having ascertained the germicide value of certain reagents for a single micro-organism, the question arises as to whether we are justified in assuming that other organisms of the same class, and especially pathogenic bacteria, will be killed by the same reagents in like proportion, or if we can generalize from the data obtained.

"The results show that, in general, those reagents which destroyed the vitality of the micrococcus from pus are fatal to organisms of the same class, and that their relative value as germicides is not changed when a different micro-organism is used as the test of this value. Moreover, the reagents which were ascertained to be practically valueless as germicides with the micrococcus from pus, for example, ferric sulphate, sodium sulphite and hyposulphite, boracic acid, etc., proved to be equally without value when the test was extended to other micro-organisms of the same class. But the reagents found to possess decided germicide power have, in some cases, a different value for different organisms. In other words, the vital resistance of various bacterial organisms to the reagents in question is not in all cases the same. Thus sulphuric acid failed to kill *B. termo* and the micrococcus of pus in the proportion of 0.25 per cent.; but one fourth of this amount (0.06 per cent.) destroyed the vitality of the septic micrococcus. Caustic potash destroyed the septic micrococcus in the proportion of two per cent., but failed to kill the micrococcus of pus in four times this amount (eight per cent.). The value as a germicide of the solution of ferric sulphate and sulphuric acid, in water, which has been extensively recommended by sanitarians as a *disinfectant*, evidently depends upon the sulphuric acid which the solution contains. To insure the destruction of all bacterial organisms and of the reproductive spores of those species which multiply by spores as well as by transverse fission, such a solution should be used in sufficient quantity to subject the material to be disinfected to the action of the acid in the proportion of at least five per cent. for a period of two hours. The quantity of carbolic acid used to accomplish the same result should not be less than this, five per cent., for it is necessary to keep on the safe side, and we do not know at present whether all of the pathogenic bacteria, hypothetical or demonstrated, form spores or otherwise. In the case of the anthrax bacillus and of Koch's bacillus of tuberculosis this has been proved to be true; and we have ample experimental evidence to show that these reproductive bodies possess very great resistance to heat and to those chemical reagents which kill bacterial organisms in their ordinary condition of rapid growth and multiplication by fission. Evidently therapeutic value, assuming the correctness of the germ theory, cannot be gauged by germicide power alone, for it is possible that a reagent which possesses this power in but slight degree, or not

at all, may nevertheless be capable of restricting the development of pathogenic organisms and thus limiting their power for mischief. The following table shows the percentage required to destroy vitality, and also that required to prevent the development of the micrococcus of pus.

Reagent.	Percentage required to destroy Vitality.	Percentage capable of preventing Development.
Mercuric bichloride.....	0.005	0.008
Iodine.....	0.3	0.025
Sulphuric acid.....	0.25	0.12
Carbolic acid.....	0.8	0.2
Salicylic acid and sodium biborate....	2.	0.5
Alcohol.....	40.	10.
Ferric sulphate.....	{ Failed in saturated solution. }	0.5
Boric acid.....		0.5
Sodic biborate.....		0.5

"An inspection of the table shows that the potent germicides in our list restrict multiplication in quantities considerably less than are required to destroy vitality. In the case of iodine the difference is eight-fold, in that of carbolic acid fourfold, in that of sulphuric acid twofold, etc.

"We also see that the agents at the bottom of the list, — ferric sulphate, boric acid, and sodium biborate, — in the proportion of five tenths per cent., prevent the multiplication of bacterial organisms, and are consequently antiseptic agents of value, although in saturated solution they fail to kill these organisms. In the case of ferric sulphate, and also of zinc sulphate and zinc chloride, this power to prevent the development of micro-organisms seems to be due to precipitation of the organic material in the nutritive medium rather than to any direct action upon the living organisms, which, as we have seen, are not killed by a far greater quantity of the reagent.

"The proportion in which mercuric bichloride prevents the development of the septic micrococcus is 0.0025 per cent., or one part in 40,000. If we suppose that there are twenty pounds of blood in a man weighing one hundred and sixty pounds, three and one half grains would be required to prevent the development of the septic micrococcus. This amount would be much too large for a single dose, but it is probable that there is an accumulation of this drug in the system from its incomplete elimination. In view of this it is not difficult to believe that mercuric bichloride may be introduced into the system in quantities sufficient to restrain the development of the parasitic micro-organism, and we will have a satisfactory explanation of the *modus operandi* of this remedy in syphilis if this is eventually demonstrated to be a "germ" disease. The drug has been found useful in diphtheria, typhoid diarrhoea, erysipelas, and dysentery. Calomel has recently been recommended as a specific during the first nine days of enteric fever. Ferric sulphate and zinc sulphate possess considerable antiseptic power, but are unreliable as antiseptics.

"It is evident that mercuric bichloride and iodine are germicide agents of the highest value; the proportion in which they would certainly be efficient may be given as 0.02 per cent., or one part in five thousand for the bichloride and one part in two hundred for iodine (dissolved in a solution of iodide of potassium). The poisonous properties and want of color of a solution of corrosive sublimate of the proper strength make this

of doubtful utility for general use in a sick room, but in iodine we have an agent which might be used for disinfecting spittoons, bed-pans, etc."

Hospital Practice and Clinical Memoranda.

A CASE OF MANUAL DILATATION OF THE OS UTERI FOR THE REMOVAL OF A DEAD FÆTUS.

BY A. WORCESTER, A. M., M. D. (HARV.)

ON August 15, 1883, during my service as house physician in the Boston Lying-In Hospital, I was called in consultation to see Mrs. S., a patient of Dr. W. A. Dunn's, under the care of his assistant, Dr. D. J. Brown. I found a pale, slightly-built woman, twenty-one years old. Two years ago her only living child was born, since when she has suffered two miscarriages. She has coughed badly for some years (fibroid phthisis being the diagnosis of her physician). She is now five and a half months pregnant. On August 12th, three days before, the membranes ruptured. On the 14th, at ten P. M., labor pains began, and Dr. Brown was summoned. He found the cord feebly pulsating in the vagina, and the os uteri barely admitting the tip of the finger. The next morning there was no change except that the pulsation in the cord had ceased. At the time of my visit she had had no pains for several hours, but complained of a dull, continuous pain in the right iliac region.

Examination revealed an entire absence of abdominal tumor. A cold and pulseless loop of the cord protruded from the vulva. The os uteri barely admitted the finger-tip, and was hard to reach. There was a distinctly offensive odor, but no discharge.

The patient was etherized, and at five P. M. manual dilatation of the os uteri was begun. The difficulty was heightened by a lateral flexion of the uterus. The fundus rested in the right iliac fossa, and although its position could be easily corrected after one finger was hooked into the cavity, it was impossible from the outside so to hold it. Despairing of introducing a second finger while the first had thus to serve as a tenaculum, the ball of the thumb was held in the internal os, and by steadily flexing the last phalanx sufficient dilatation was obtained to allow two fingers to enter the cervix. Twice the operation was suspended that the patient might clear her trachea. Instead of occasional contractions of the uterus it seemed as if there were only occasional relaxations. As soon as the legs of the fetus could be reached they were drawn down, and, owing to insufficient dilatation, were torn off. The body was removed piecemeal. In spite of care not to separate the placenta, which could easily be felt on the right side, before the head was extracted, a hæmorrhage began. With a pocket-case needle holder I succeeded in perforating, and smashing, and extracting the head. The placenta was partially adherent. After tearing away what I could the uterine walls were rubbed clean with the fingers. The hæmorrhage was not controlled until hot and cold intra-uterine douches were alternately given. The operation lasted two hours. As a precautionary measure intra-uterine douches were given the four following mornings. Convalescence normal. On the tenth day she sat up, and a month after is reported doing nicely.

New Instruments.

A NEW DECAPITATING INSTRUMENT.

THE operation of decapitation is rarely called for, but when required the better the instrument obtainable the more easily the operation can be done.

Decapitation is called for in an impacted shoulder presentation, when the shoulder is jammed into the pelvic brim so that it is impossible to use forceps or do version. In these cases the membranes are likely to have been long ruptured, permitting the liquor amnii to drain away, and the uterus, unable to overcome the obstruction and empty itself, is generally in a state of tonic contraction around the child. Often in those cases that have gone on for some time without the requisite assistance one arm of the child is found prolapsed into the vagina with the hand showing at or near the vulva. Decapitation is taking the place of craniotomy in cases of this kind, and should always be done when the neck can be reached.

The old operation was to insert a blunt hook under the neck of the child with the point upwards toward the bladder, then, being sure that the instrument was in position, and having guarded its point with the left forefinger, the handle was turned a little to carry the point away from the head, and drawing down upon the handle towards the perineum a quick turn was given the instrument, and the neck was broken, then by twisting the hook around several times the head was severed from the body.

During the past few years Dr. W. L. Richardson has been using in his operative course at the Harvard Medical School a cutting hook together with the blunt hook. He uses the blunt hook to break the neck, but does not twist the neck off with it as in the old operation. Having broken the neck the blunt hook is removed, and a cutting hook, with an internal sharp edge, is inserted over the neck, with the point downwards, away from the bladder; the forefinger of the operator's left hand is then placed upon the end of the hook to protect the soft parts of the woman, while with a slight up and down motion of the handle, and traction with the right hand, the neck is severed.

This operation is far preferable to the old one, but necessitates the introduction of two hooks, the blunt and the sharp, which is difficult to do when the shoulder is firmly impacted. To obviate this difficulty as far as possible I have had made the instrument shown in the diagrams. It is nothing more than the blunt

movement of the handle, the point of the instrument being protected by the left forefinger, the head is separated from the body. The head slipping up, the body of the child is drawn out by the prolapsed arm, the operator's fingers of one hand covering the sharp cervical vertebrae. The head is then removed with the forceps, care being taken that the ragged part comes between the blades.

The instrument is very simple, easily cleaned, and not expensive, and by having the two instruments combined in one the difficulty of inserting two separate instruments is avoided.

ROBERT B. DIXON, M. D.

Boston, September 10, 1883.

Reports of Societies.

QUARTERLY MEETING OF THE RHODE ISLAND MEDICAL SOCIETY.

A QUARTERLY meeting of the Rhode Island Medical Society was held in Newport, September 20, 1883, the President, DR. JOB KENTON, in the chair. This was the first meeting of the Society held in Newport for twenty-three years, though in its early days every alternate meeting was held in that city.

The secretary, DR. G. D. HERSEY, exhibited reels of Pancoast's

BLACK IRON-DYED SURGICAL SILK,

which is furnished in fourteen sizes. The finest sizes are adapted to plastic surgery and delicate operations, the medium sizes to ordinary operations, and the strongest when great strength of ligature is required.

In operations like circumcision where considerable oedema of the parts is apt to conceal the sutures the black silk is more readily seen than the white, and may be removed with less disturbance of the flaps.

Successful removal of sutures is often a matter of great importance, as in ophthalmic and plastic operations where the slightest injury to the newly united edges is to be avoided; and it is in these cases that the black silk is especially useful. Moreover, this silk, dyed with iron, is less irritating to the flesh than white lead-dyed silk, and sutures will remain a long time without causing inflammatory action.

DR. W. E. ANTHONY read a paper on the

MANAGEMENT OF THE THIRD STAGE OF LABOR,

advocating immediate delivery of the placenta. The doubling together of the detached placenta and its expulsion with the axis of the folded mass parallel with the axis of the maternal passages appears to be the natural

mechanism of placental delivery. Thus one edge of the placenta should appear first at the vaginal outlet. Traction on the cord causes an unnatural presentation of the broad fetal surface, the placenta resembling an inverted umbrella. The author adopts Credé's method for the removal of the after-birth, — preparing for expression of the placenta by grasping the uterus during the latter part of the second stage of labor and compressing it during a pain, following the womb as it is gradually emptied, keeping

and sharp hooks combined. The larger diagram shows the instrument as it should be when inserted over the neck of the child, and by the method already described the neck is broken. Without removing the instrument, but by simply turning the thumb-screw, B, a concealed

knife, A, is drawn out one fourth of an inch on the inner side of the blunt hook, and by traction, accompanied by the simple up and down

up continuous pressure during and after the expulsion of the child, and allowing no cessation of uterine action until delivery is fully accomplished. Should there be any delay in the delivery of the placenta, the following procedure is advised: without relaxing the grasp on the uterus, pass the fingers of the unoccupied hand into the vagina and uterus; if necessary, detach and remove the placenta immediately. The relaxation and temporary anæsthesia of the parts following child-birth favor this manœuvre.

The following direct advantages were claimed for immediate placental delivery: Security against post-partum hæmorrhage, uterine inertia, retained placenta or fragments, severe protracted after-pains, prolonged lochial discharge, and septicæmia. Moreover, it saves time, and is in accordance with natural indications.

DR. D. H. BATCHELDER believed that there are few perfectly normal deliveries, because the placenta is not uniformly attached to the fundus. The severest pains are felt in the direction opposite to the attachment of the placenta,—thus front pains indicate a posterior attachment, while anterior attachment of the placenta is accompanied with posterior pains and back-ache.

In two cases of rupture of the uterus the placenta was attached low down and posteriorly, and rupture was at the opposite side,—in front, confirming the view that the strongest uterine contractions are opposite the placental attachment. Traction on the cord in delivery of the after-birth is permissible if one inserts a finger to pull down one edge of the placenta. An assistant should press on the fundus.

DR. S. W. FRANCIS reported a case of

PROBABLE EPITHELIOMA CURED BY ASTRINGENT WASHES.

Mrs. B. had a circumscribed induration as large as an almond in the cheek, having its mucous surface much eroded by contact with the sharp edges of a tooth cavity. The offending tooth was at once extracted, but the removal of the local irritant was followed by no improvement in the bad appearance of the inner cheek. The swelling and induration became greatly increased and extended forward so as to produce very marked external deformity. Dr. Francis treated the case as follows:—

R Tinct. opii	3 ss.
Tinct. myrrhæ	aa 3 i.
Glycerine	
Squibb's liq. ferri subsulph.	3 ss.
Aque rosæ	q. s. ad 3 iv.

M. S. Apply one teaspoonful of mixture to inside of affected cheek four times a day.

In addition to this local treatment the patient was ordered milk diet, with strong broth, and twenty drops of the syrup of iodide of iron, three times a day. In three weeks seven eighths of the enlargement and induration were gone, the cheek and lip became thin and flexible, and all the angry appearance had vanished. This case was reported to illustrate the wisdom of first employing mild measures before resorting to the knife.

REPRODUCTION OF FIRST PHALANX OF INDEX FINGER.

DR. O'LEARY reported the case of a boy with lacerated wound of the index finger and compound fracture of the first phalanx apparently demanding amputation, but as it was not convenient to etherize the patient, treatment at the hospital was recommended. The boy, how-

ever, did not go to the hospital, but reappeared three weeks later with bare bone protruding from the wound. The entire phalanx was found detached from the periosteum and was removed. Bone was reproduced, and the patient now has a strong finger with movable joint.

DR. EZRA DYER exhibited

A NEW PERIMETER.

which consists of a spiral wire forming a hemisphere of about the same diameter as Förster's perimeter. Within the hemisphere is a revolving arm in the form of a quadrant carrying a traveler which follows the spiral wire. The object for testing the field is attached to the traveler. The patient's chin, as in similar instruments, is placed upon a rest with the eye to be tested fixed on an objective button at the inner end of the central axis of the instrument. The revolution of the arm carries the traveler rapidly or slowly, as desired, over the whole field of vision. The exact boundaries of impaired vision are determined by graduations on the revolving arm, and by a graduated disk back of the central axis, where a needle indicates the meridian.

Quantitative perception of light can be determined by attaching to the traveler a small electric light supplied by a Smee battery, by which the intensity of the current can be regulated to produce any light, from a dull cherry red to the brightest possible. By placing colored disks on the traveler, the same instrument can be used to detect eccentric color-blindness.

DR. H. G. MILLER reported a case of

CHOROID DISEASE WITH PIGMENTED PATCHES,

which varied in color, size, and position. The patient was able to observe his own symptoms very closely, and made a series of beautiful illustrations of the changing colored spots. Dr. Miller exhibited the pictures, remarking that it would be fortunate if patients could oftener assist their physician as intelligently.

DR. T. W. PERRY reported a case of

EXFOLIATIVE DERMATITIS.

The patient, a middle-aged Englishman, had a chill June 12th, with intense redness of the skin. Desquamation took place on the fourth day, and extended over the entire body. The patches from the palms of the hands and soles of the feet were thick like leather. The epidermal covering of one finger was removed entire like a glove finger. The chill recurred July 3d, July 29th, and August 11th, and each chill was followed by desquamation on the fourth day. There were no other symptoms besides the chill, intense hyperæmia of the skin, and desquamation.

He had a similar attack thirteen years ago, when he recovered under arsenic, iron, and cod-liver oil. Same treatment for this attack with addition of calcium sulphide. Cod-liver oil was found to be the most soothing local application to the tender skin after the exfoliation.

MEDICAL EXAMINERS.

The committee on the proposed law regarding a system of medical examiners in Rhode Island reported through the chairman, Dr. Ariel Ballou, "that further time was needed for the study of the subject, and the committee present no report, but wish a free discussion of the subject."

DR. S. W. FRANCIS, another member of the committee, had sent a circular to each town clerk in the

State, asking the number of coroners in the town, how elected, and occupation. Replies were received from thirteen towns and cities. In five the trial justice acts as coroner, in eight coroners are elected by the town council. The latter, including Providence and Newport, have in all twenty coroners, of whom only two are physicians. The list includes three lawyers, two town clerks, two farmers, a grocer, clerk, accountant, correspondent, auctioneer, undertaker, station agent, overseer of the poor, etc.

DR. H. R. STORER, who read the above report, called attention to the utter lack of training which these miscellaneous occupations give for the responsible duties of the office. Under the proposed law the medical examiner's duty ends with rendering a decision whether or not murder has been committed. The case then passes to the trial justice of the town or city, who hears the evidence, and conducts the preliminary trial of the suspected person.

DR. HENRY W. WILLIAMS, of Boston, explained in detail the origin and present working of the Massachusetts system of medical examiners. The office is filled in that State by seventy first-class men, and the public, as well as prosecuting officers, are better satisfied than with the old system.

Replying to numerous inquiries, Dr. Williams said that the cost to the State was reduced to two thirds the cost of the old system. In Suffolk County the gain was even greater.

Politically speaking, the reduction of cost was satisfactory, and scientifically speaking, the results are emphatically a great improvement.

Concerning the limit of age, twenty-five to forty-five, in the proposed law, he disapproved that limit. Few men under thirty are qualified for such work, and the best man for the position might be forty-six.

DR. STORER, defending the last clause, thought that the younger men are better educated in this comparatively new science, and more alive to the interests of a new law.

DR. STIMSON inquired whether the medical examiner's jurisdiction should include all cases of sudden death.

DR. STORER thought that there ought always to be some investigation of sudden death, as otherwise cases of poisoning might escape detection.

The subject was referred back to the committee with instructions to collect further information and report at the quarterly meeting in December. Drs. Lloyd Morton, of Pawtucket, and H. G. Miller, of Providence, were added to the committee.

The Society are unanimously in favor of a change in the present law, and will undoubtedly make strenuous efforts for reform.

ELECTION OF FELLOWS.

As recommended by the Board of Censors, Drs. A. H. Harrington, of Providence, J. P. Sweeney, of Central Falls, Henry Arnold, of Foster, George V. Foster, of Westerly, and Ezra Dyer, of Newport, were elected Fellows.

REGISTRATION OF DEATHS.

DR. HENRY E. TURNER called attention to the fact that physicians too often leave to the undertakers all responsibility concerning death certificates, not giving a certificate unless the undertaker asks for one. On

this motion the Committee on Medical Examiners are also requested to report whether the present law concerning the registration of deaths can be more thoroughly enforced.

THE AMERICAN GYNECOLOGICAL SOCIETY.

THE eighth annual meeting of the American Gynecological Society convened in Philadelphia, September 18th, and remained in session three days. The meeting was held in the College of Physicians.

FIRST DAY. MORNING SESSION.

Dr. Gilman Kimball, of Lowell, Massachusetts, President of the Society, in the chair. The meeting was called to order at ten o'clock, and the following members were recorded as present by the Secretary, Dr. Frank P. Foster, of New York: Fordyce Barker, New York; Robert Battey, Georgia; B. B. Browne, Baltimore; Wm. H. Byford, Chicago; John Byrne, Brooklyn, New York; H. F. Campbell, Georgia; Jas. R. Chadwick, Boston; E. L. Duer, Philadelphia; T. A. Emmet, New York; F. P. Foster, New York; Wm. Goodell, Philadelphia; Wm. T. Howard, Baltimore; J. V. Ingham, Philadelphia; A. Reeves Jackson, Chicago; J. T. Johnson, Washington; Gilman Kimball, of Lowell, Massachusetts; W. T. Lusk, New York; M. D. Mann, Buffalo; C. D. Palmer, Cincinnati; Theophilus Parvin, Philadelphia; Thaddeus A. Reamy, Cincinnati; J. C. Reeve, Dayton; A. H. Smith, Philadelphia; R. S. Sutton, Pittsburg; H. P. C. Wilson, Baltimore; Elwood Wilson, Philadelphia; Ely Van de Warker, Syracuse.

The names of a number of invited guests were read by the Secretary, as recommended by the Council.

ADDRESS OF WELCOME.

DR. E. L. DUER of Philadelphia, delivered a brief address of welcome on behalf of the Philadelphia members.

SUPERINVOLUTION OF THE UTERUS.

DR. JOSEPH TABER JOHNSON, of Baltimore, read a paper describing a condition first described by Sir James Simpson as superinvolution of the uterus. Although Sir James carefully described this some thirty years ago, stating that his patients derived very little benefit from treatment, the subject is very infrequently referred to in the text-books; although it is not uncommon, and Simpson thought that the number of cases would be found to be very large if properly looked for. It is to be distinguished from atre-ia of the uterus after labor, and he limited the term to a condition of excessive involution occurring after the uterus has been emptied of some mass, normal or abnormal, which had distended it beyond its ordinary capacity,—as in hydro-metria, pyrometria, hydatids, fibroid or other tumors, dropsy of the amnion, or after ordinary gestation or abortion.

He related the history of four cases in his own practice, in which the results of the treatment had not been very encouraging, but they were as good as those reported by others. Simpson reported several, with no other result. Whitehead reported a case in which the uterus completely disappeared after labor. Scanzoni recognizes labor as a cause of atrophy of the ovaries. Prolonged lactation has been assigned as a cause of superinvolution of the uterus, but this was

not the case in one of his patients at least, for the child was still-born. Dr. Edes states that in some cases the one supreme effort at reproduction entirely exhausts the procreative power, and atrophy follows.

DR. BARKER, in opening the discussion, believed that it would be proper to extend the application of the term *superinvolution* to a series of cases in which a similar condition occurs after uterine fibroids, in which retrograde processes sometimes proceed to an extreme extent. With regard to the relative frequency of these cases, it will be acknowledged that a consultant would be likely to see them much oftener than other practitioners. He saw in his own practice two or three cases every year; he thought that while it is comparatively rare, it occurred quite as frequently as stated. There is an important point in the prognosis and treatment. Where there are signs of constitutional disturbance each month indicating functional activity of the ovaries, treatment may be of service; where the ovaries are atrophied, and no symptoms of ovulation occur, he would not expect much from treatment. He reported the details of a case that he had under systematic treatment for three years. He applied electricity, and gave pills of aloes, sulphate of iron, etc., dilated the cervix, and succeeded in establishing menstruation. She was subsequently delivered of a living child. In another case a lady had had a miscarriage, while traveling in Europe, from overfatigue. She had great hæmorrhage, and did not menstruate afterwards. There was this condition of *superinvolution*, but each month great constitutional disturbance was manifested. After a similar course of treatment she conceived, and had a living child.

The main point is that where *superinvolution* is associated with functional activity of the ovaries we may have great hope of restoring the uterus, but where they have lost their activity treatment is of little use.

DR. A. REEVES JACKSON considered it of importance to distinguish between *superinvolution* of the uterus and the early appearance of the climacteric, in considering the advantages of treatment. He had been surprised at the statement as to the relative frequency of *superinvolution*. He had himself seen but a single case, and this was of doubtful diagnosis. In introducing the probe in this case he penetrated the uterine fundus, but was much relieved by finding no bad results following it. Whether the atrophy arises from a local or a general cause is of great practical importance as regards the treatment, and he, therefore, approved the distinction made by Dr. Barker.

DR. VAN DE WARKER called attention to a possible source of error. Some cases of laceration after labor are followed by atrophy of the cervix, which would shorten the canal, and might lead to the idea of *superinvolution*. If this were the case, it would be easy to explain the supposed comparative frequency of the condition. He thought that Dr. Johnson's second case might have been of this kind.

DR. WILSON, of Baltimore, regarded the condition as extremely rare; in all his practice he had seen only two or three cases. He approved of the views of Dr. Barker as to those which are susceptible to improvement, and those which are not.

DR. BATTEY considered *superinvolution* of the uterus the natural result of removal of the ovaries in his operation. In some cases it had been extreme. He attributed the condition to the ovaries rather than the uterus. He had never seen it after removal simply of

the Fallopian tubes. In the treatment he approved of electricity and dilatation of the canal with sponge tents.

DR. BYFORD said that there was considerable confusion concerning the exact meaning of *superinvolution* as distinct from *subinvolution* or *hyperinvolution*, owing to want of definite knowledge. Is *superinvolution* a stage in a progress to atrophy? He believed that there is a decided difference between *superinvolution* and atrophy, but in the great majority of cases what is called *superinvolution* is an early stage of atrophy. In *superinvolution* the uterus, though reduced, still continues its ordinary characters and its normal innervation. He thought with Dr. Barker that these cases may be divided into those with simple uterine *superinvolution* and those complicated with ovarian disorder. Where the ovaries are much reduced by *superinvolution* the uterus must necessarily become so, but where they still retain their functional activity the case may be cured.

DR. CAMPBELL did not regard it as necessary for *superinvolution* of the uterus to occur, that there should be either atresia of its cavity, or atrophy of the ovaries. He reported a case in which *superinvolution* followed extreme distention of the uterus by dropsy of the amnion. Although the patient had been regular before and had had children every year, she never menstruated again. The over-distention had the same effect upon the uterine muscles as it sometimes has on the bladder.

DR. JOHNSON, replying to Dr. Van de Warker, stated that he had at first supposed the second case to be one of atrophy due simply to the cervical laceration, but had given up this opinion, because he had operated upon the cervix and restored it, and yet she never had menstruated. In reply to Dr. Jackson, he said that he had not claimed that the disorder is very frequent, but that it is frequent enough to deserve more attention. The point raised by Dr. Barker is important both as to prognosis and treatment.

THE IMPORTANCE OF CLEANLINESS IN SURGICAL OPERATIONS.

DR. R. STANSBURY SUTTON read a paper embodying his impressions of a visit to the European hospitals, particularly with reference to the general adoption of the principles of Listerism. Although minor differences of application were found, some using the spray, others not, some using carbolic acid, others discarding it entirely, the greatest care was now manifested with regard to cleanliness after surgical operations, to avoid contamination of wounds. He contended that this great change had been brought about through the teachings of Lister, and that the profession owed a great debt of gratitude to him for the great advance in practical surgery.

DR. EMMET spoke in favor of cleanliness, and repeated what he had elsewhere said, that the death warrant of the patient is often carried under the finger-nail of the surgeon.

DR. LUSK uses the spray in operations in the wards of Bellevue Hospital, with satisfactory results, and could perform operations successfully with its aid which without it were uniformly fatal.

DR. WILSON, of Baltimore, used the spray in the room before the operation, not during operation.

DR. CAMPBELL thought that too much credit was given to Mr. Lister by ascribing to him all the cleanliness in surgical operations. Some surgeons were clean

before Mr. Lister came. Referring to the statistics he could not say that the results after amputations were any more favorable since the introduction of carbolic acid than they were before. He referred to a case, where after amputation of a thigh delirium and symptoms of prostration appeared. He advised that the carbolic acid be stopped, and the patient recovered promptly.

DR. SUTTON denied that carbolic acid and Listerism are synonymous, and he claimed that even those who were most outspoken in denouncing Listerian treatment had adopted its principle in their practice.

AFTERNOON SESSION.

HOT WATER IN SECONDARY HÆMORRHAGE AFTER PELVIC OPERATIONS.

DR. ALBERT H. SMITH, of Philadelphia, regarded hot water at a temperature of 115° F. to 120° F., as an efficient hæmostatic, not only in obstetric practice but also after surgical operations. He employed it regularly after every case of labor (slightly tincturing it with some form of antiseptic) in order to obviate hæmorrhage, and continued the irrigation until the water came away perfectly clear. He wished in this communication to call attention to the use of this agent in plastic operations, even where bleeding occurs from moderately large vessels. Referring to cases reported by Dr. Skene, he was surprised to notice that he had been unable to control hæmorrhage; the speaker was confident that hot water will arrest bleeding in just such cases. After relating the clinical history of such a case he directed attention in conclusion to three points: (1) The great advantage of this agent over all others for arresting secondary hæmorrhage after pelvic operations; (2) its efficiency when it is carried to the bleeding surface; and (3) its simplicity and convenience of application.

DR. REAMY approved of hot water as a hæmostatic, and in operations upon the perinæum he is accustomed to keep a stream of it flowing over the surface.

DR. CAMPBELL, in post-partum hæmorrhage, was perfectly satisfied with iodine injections, as recommended by Dr. Trask (one part compound tincture of iodine to four of water). He called attention to a form of uterine dilator known as the metroclast for use in making intra-uterine injections, permitting free outlet for the water.

DR. MANN mentioned a case of amputation of the cervix where the hot water failed to check hæmorrhage. He then applied Pacquelin's cautery, and tamponed, but the patient died in ten minutes from loss of blood. Dr. Mundé had reported a similar case.

DR. GOODELL thought that Dr. Mann had expected too much from the hot water. In post-partum hæmorrhage he would prefer hot vinegar. After operations, hot water applied to the bleeding surface will usually check the hæmorrhage.

DR. BARKER said that hot water requires several minutes before stopping the bleeding, but cases occur in which even this delay is a serious matter. In one case where the hæmorrhage was very great he had succeeded in checking it by dipping cotton in fluid extract of ergot and applying it to the bleeding surface of a cauter of the cervix, confining it with a tampon.

DR. CAMPBELL said that in post-partum hæmorrhage anything which will stimulate the uterus to contract will check the bleeding. This is the great value

of iodine; it is not a styptic in itself, but it causes contraction of the uterus, and closes the bleeding sinuses. Now, in uterine cancer and after operations an agent is needed that will cause coagulation of blood in the vessels, such as hot water or other hæmostatics.

DR. SMITH, in closing the discussion, attributed the failure in Dr. Mann's case to the difficulty of applying the hot douche to the bleeding surface. He thought it might be done by elevating the hips of the patient so that the blood might gravitate to the upper portion of the body. If this is done the specific action of the hot water upon the surface can be attained. He said that Dr. Goodell's suggestion to medicate the hot water with vinegar was similar to the use of other antiseptics which he had mentioned. He regarded hot water as the most important element.

DYSMENORRHOEA.

DR. C. D. PALMER, of Cincinnati, read an admirable paper on Some Points Connected with the Subject of Dysmenorrhœa. The object of this communication was to establish the fact that the causes of dysmenorrhœa are not local, but general; it is not due to mechanical causes, but is essentially a neurosis. All the abnormalities of the uterus which have been given as the cause of dysmenorrhœa may exist without producing these symptoms, and even where they do exist the extent of the abnormality and the severity of the attendant symptoms are not proportional.

Local treatment may be required, but always conjoined with systemic treatment. Of the remedies, arsenic and iron are most important; iron, where there is marked anæmia and scanty flow; arsenic, where the flow is irregular and profuse. He recommended a combination of iron, in the form of sulphate, carbonate or chloride, and *nux vomica* or phosphorus; cod-liver oil and quinine may also be given with advantage. Galvanism is very useful, the cathode over the hypogastric region, and the anode applied to the perinæum or along the spine; this is especially indicated in the purely neurotic or spasmodic form of the disease. In such cases the old mixture of mercuric chloride and potassium iodide he had used with great relief. Concentrated tincture of *Cimicifuga racemosa* given in the intervals, and in small doses during the paroxysms, is useful in spasmodic cases; tincture of *pulsatilla* is also useful. He referred to the abuse of narcotics in these cases; opium, chloral, etc., do not cure the trouble but only render it more difficult to cure by favoring a condition of the nervous system which continues the disease.

In stenosis dilatation of the cervix by bougies is useful and also in the purely neurotic form, because it makes the mucous membrane less sensitive. He believed that the operation of incision was too much relied upon, and its results overrated. The stenosis is usually at the inner os, which explains why such cases are usually barren.

DR. CHADWICK said that to a very large extent he had given up the idea of obstructive dysmenorrhœa. The spasmodic contraction of the uterus is a peristaltic movement of the muscles caused by irritation. This in some cases is due to catarrh, when the neurotic element is strong. He recalled two cases in which he could discover no local cause whatever. Regarding them as instances of general disturbance of the nervous system due to the menstruation, he gave the bromide of sodium (gr. xx. t. d.) before the period, and fluid

extract of coca and chloride of ammonium, with good results.

DR. BARKER thought that the cases of mechanical dysmenorrhœa are comparatively rare. He believed that there is no functional disorder of the woman in which it is more necessary to make a careful diagnosis than in dysmenorrhœa. He believed that in some the uterus is at fault, in others the ovaries; in the first, pain continues during the discharge; in the second, it is relieved by the discharge.

With regard to the treatment: he most frequently uses the lactate of iron in three to five grain doses three times a day, usually associated with chlorate of potassium, which has a very good effect in modifying the condition of these organs, commencing this course about ten or twelve days before the menstrual period appears. In the interval there is one remedy which nearly approaches a specific, it is a pill, given in capsules, two after each meal, to be continued through the menstrual period.

There is another class of cases in which the pain does not appear until the period is on for two or three days, in strong young women with strong vitality. Here there is too much ovarian excitement. In these cases bromide of sodium in fifteen to twenty grain doses in the middle of the forenoon, afternoon, and at bedtime. This is likely to occur in young widows, who had good health before; nothing abnormal is detected upon vaginal examination to account for the dysmenorrhœa.

SECOND DAY. MORNING SESSION.

DR. GILMAN KIMBALL, of Lowell, Massachusetts, delivered the

ANNUAL ADDRESS OF THE PRESIDENT.

He selected for his subject Dr. Nathan Smith, of Dartmouth College, of whom he gave a biographical sketch. Dr. Smith performed ovariectomy successfully at Norwich, Vt., in 1821, without being aware that he had been anticipated by McDowell. This was the second successful operation in this country, and was as truly original as that performed by McDowell. Without disputing the position of McDowell as the father of ovariectomy, the justice of whose claim is now acknowledged everywhere, he wished still to pay this tribute to Dr. Smith, whose genius, indomitable will, and untiring energy had done more for practical medicine and surgery than that of any other individual in this country. In point of absolute merit Smith stands beside McDowell.

PROFESSOR GROSS made a few remarks upon the paper, reaffirming McDowell's claims as the originator of ovariectomy.

A RARE FORM OF ABDOMINAL TUMOR.

DR. THADDEUS REAMY, of Cincinnati, related the histories of three cases of abdominal growth, which on tapping were found to contain blood. The two which were tapped recovered, the third died, and upon examination the tumor was discovered to be a sarcoma of the omentum.

DR. LEE advocated tapping as an aid to diagnosis.

DR. SUTTON did not believe that a diagnosis could be made during life between cancer and sarcoma of the omentum. He would prefer abdominal section for diagnostic purposes.

DR. CAMPBELL thought that as such growths are

apt to be pedunculated he would advocate their removal even if they were malignant; it is proper to give the patient the benefit of the operation.

DR. REAMY would not approve of the doctrine advocated by Dr. Sutton, who claimed that it would be more judicious to open the abdominal cavity than to tap. The hypodermic needle would remove enough fluid for diagnostic purposes, and tapping in at least one case was followed by a return to robust health.

A paper on A New Method of Operating for Fistula in Ano was read by title, in the absence of the author, Dr. E. W. Jenks, of Chicago.

CONGENITAL FISSURE OF THE FEMALE URETHRA WITH EXSTROPHY OF THE BLADDER.

DR. HENRY F. CAMPBELL, of Georgia, read a clinical paper on Congenital Fissure of the Female Urethra with Exstrophy of the Bladder, and reported a case in a child two years of age. He inquired what would be the best time for operating, at an early age before the parts had developed, or after attaining puberty?

DR. MANN referred to a case in which early operation had been performed with satisfactory results.

DR. BROWN, of Baltimore, mentioned a case of this kind with a calculus in the ureter; operation was declined, and the patient died.

DR. CAMPBELL said that he had feared that the necessary removal of tissue in paring the edges might remove some that would contribute to further development. The inquiry was altogether in the interest of the patient.

A STUDY OF THE ÆTIOLOGY OF PERINEAL LACERATION WITH A NEW METHOD FOR ITS PROPER REPAIR.

DR. EMMET invited attention to a subject which had claimed very much of his attention during the past twenty years. He had become convinced that simple laceration of the perinæum, not involving the sphincter, was not really the cause of the many symptoms which had been attributed to it; even after healing the irritation from the cicatrix was slight. Laceration of the perinæum may be present without any of the so-called symptoms, and on the other hand, such symptoms may be present to a marked degree without any laceration whatever. He insisted that the perinæum does not support the vagina and uterus, as commonly taught, but that a more important structure is concerned. He discussed the anatomy of the pelvic fascia, and showed its sheath surrounding the vagina, and passing to the brim of the pelvis. This sheath of fascia may be ruptured with or without any external laceration. He claimed that where it is ruptured, the posterior wall of the vagina rolls downward and outward, so that if there happen to be a perineal laceration, it appears greatly exaggerated. He claimed that the proper mode of repairing such lacerations is to make two crescentic denudations in the posterior surface of the vaginal wall, which, when brought together, will bring the stitches entirely within the vagina.

The discussion of the paper was postponed to the afternoon session.

AFTERNOON SESSION.

DR. EMMET gave a résumé of his paper on

LACERATION OF THE PERINÆUM.

He claimed that laceration of the perinæum does not give rise to the symptoms which have been attributed

to it. The laceration is never so extensive as it appears. There is no such body in existence as the so-called perineal body, to restore which is supposed to be the object of the operation. The object of the operation really should be to bring up the posterior wall of the vagina in contact with the anterior wall and prevent ballooning. By his operation this is attained, and any perineal laceration may be disregarded or treated, it matters little whether it is attended to or not. The point is that the support is afforded by the pelvic fascia, and wherever the posterior wall of the vagina drops away from the anterior it is evident that the fascia is at fault.

A general discussion followed this paper, but as it was evident that the lecturer and his auditors did not fully understand each other, Dr. Emmet begged that they would reserve their judgment until they had an opportunity of reading his paper.

ACCIDENTAL PUNCTURE OF THE UTERUS IN LAPAROTOMY.

DR. C. C. LEE, of New York, read a paper on the Management of Accidental Punctures and other Injuries of the Gravid Uterus as a Complication of Ovariectomy, in which he gave the details of seven cases, including one of his own.

First. The pregnant womb may be punctured or otherwise wounded during laparotomy without necessarily causing abortion.

Second. Miscarriage seems, both *a priori* and from clinical evidence, to depend upon injury of the uterine contents, not of the womb itself, however severe.

Third. If the former has certainly occurred, Cæsarean section is indicated, and should be promptly performed. In this case the utmost care must be subsequently taken to secure thorough drainage from the uterine cavity.

Fourth. If the uterine walls alone are injured the wound is to be treated on general principles. If a deep puncture or incision, it must be sutured with the minutest care, with exact coaptation of the edges. For this purpose fine silk sutures, rendered antiseptic, are the best. If a nick or superficial puncture, it must not be ligated, for ligatures cut quickly through uterine tissue; if too small to be sutured the bleeding points must be lightly touched with the thermal cautery until oozing has ceased. Good surgery and the dictates of humanity alike demand that under such circumstances a chance of survival be given the child as well as the mother.

The paper was discussed by DR. WILSON, of Baltimore, who reported a case, DR. GARRIGUES, and DR. BYFORD.

EXTIRPATION OF THE CANCEROUS UTERUS.

DR. REEVES JACKSON, of Chicago, read a paper entitled Is Extirpation of the Cancerous Uterus a Justifiable Operation? The answer was that it was not justified by the results, as cancers show great liability to return, and the operation itself is highly dangerous. The diagnosis cannot be made sufficiently early to afford any hope of cure by Freund's operation, as it is called.

DRS. VAN DE WARKER, EMMET, PALMER, and BAKER indorsed the author's conclusion, and preferred local treatment.

DR. SUTTON, of Pittsburg, believed that the opera-

tion offered the only chance for life, and described the methods of operation by Schroeder and Martin.

DR. JACKSON said that the operation had one recommendation, it usually relieved the patients of their sufferings very effectually. He compared it with a game of chance where the gamester stakes what he does not own — the life of his patient — on a desperate hazard.

Recent Literature.

Anatomy, Descriptive and Surgical. By HENRY GRAY, F. R. S. With an Introduction on General Anatomy and Development, by T. HOLMES, M. A. Edited by T. PICKERING PICK. A new American from the Tenth English Edition. Henry C. Lea, Son & Co. 1883.

The last American edition of this standard text-book appeared in 1878, and, as the original has been twice revised since, we are glad to welcome this new issue, which is from the tenth English edition. The general character of the book is unchanged, but in some respects it is much improved. The histology has received much attention and is very fair. Perhaps, indeed, we should speak more strongly in its favor, and we think we may say that it is as complete as it is desirable that histology should be when forming part of an anatomical text-book for students. Very much the same may be said of the embryology. There are several new plates in the body of the work. We are particularly glad to see some good views of the topographical relations of the thoracic and abdominal viscera. The section on the brain is more thoroughly illustrated. We regret to see a serious error, to which we called attention five years ago, still uncorrected. We refer to the parieto-occipital fissure in figure 376, page 625. We can only say that if this fissure really be the one so named in the plate, the specimen is quite abnormal. A new and welcome feature is a diagram of the course of the fibres in the medulla. The arachnoid is no longer described as a serous membrane. We find the minute anatomy of the liver and kidney very good, but we wish that in the coarse anatomy of the former organ recent researches had been noticed to the extent of changing the posterior border into the posterior surface. The retention of the system of nine pairs of cranial nerves seems perfectly inexcusable, and from a practical point of view a serious defect. The publishers have, as before, added Holden's excellent Landmarks, which are the more useful from Dr. W. W. Keen's judicious additions. We are surprised that the statement that the surgeon can reach the beginning of the œsophagus with his finger is still allowed to stand.

To return to the work as a whole: we find that it still offers opportunity for severe criticism; but with all its defects it is a work that is, and will be, a favorite with the student. It is very practical, the plates for the most part are very good, and it is not too large. It is probably the best work to recommend to the average student.

T. D.

— The sum of \$50,000 has been voted for the erection of a physiological laboratory for Dr. Burdon-Sanderson at Oxford.

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 27, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,

NO. 4 PARK STREET, BOSTON, MASS.

SOCIETIES FOR THE PROPAGATION OF CREMATION, AND THEIR HOBBY.

THE advocates of cremation in Italy and France who, if not very numerous, resemble the prohibitionists with us in another respect, as being very ardent and sometimes intemperate in season and out of season, have recently seized upon two occurrences to work their cause "for all it is worth."

The occasion seized upon in Italy was the wish of Garibaldi, as expressed in his will, that his body should be burned, a wish disregarded by his family. The occasion selected in France was the outbreak of the Egyptian epidemic of cholera.

At the time of Garibaldi's death much dissatisfaction was expressed by the cremationists at the violation by the family of the popular hero's testamentary desires in regard to the disposition of his remains, and this to the enthusiastic cremationist was unquestionably a sad blow, for nothing could so help to popularize the cause which the cremationist has at heart as the practice of his pet method for disposing of the dead upon the mortal tenement of a popular idol. The Italian cremationists, however, have taken counsel and heart of grace, and do not propose to be foiled so easily of their prey.

A letter has been addressed by the "Presidency of the Central Committee of the League of the Italian Societies for Cremation" to the Garibaldi family and to the President of the Council of Ministers of Italy, in which a somewhat long preamble of virtuous sentiments leads up to a resolve that all possible pressure be brought to bear upon the Italian government and the Garibaldi family to the end that "on the occasion of the first anniversary of the death of the great captain his body should be burned at Caprera." The letter is so good an exhibit of the eager agitator possessed with the one thing needful to renovate the living as well as the dead that we cannot forbear to give it entire:—

THE CREMATION OF THE REMAINS OF GENERAL GARIBALDI.

The Presidency of the Central Committee of the League of the Italian Societies for Cremation has addressed the following notice to the Garibaldi family and to the President of the Council of Ministers (of Italy):—

It is not very long ago since the whole of Italy was profoundly afflicted while deploring the loss of the great citizen whose actions were a memorable example of the deepest devotion to country, to liberty, and to truth.

Notwithstanding this grief there was universal applause at the news that the hero by an act of his last will had ordered that his remains should be burned as soon as possible after his death. Every one understood that this great act, inspired by the highest sentiments of our time, would exercise the greatest moral influence upon our people. Unfortunately these manifestations of general approbation were quickly followed by a feeling of astonishment and deep regret, not less general, on hearing that the family of the hero refused to carry out the solemn testamentary disposition of his own remains.

We will not discuss, nor will we even seek to know, the feelings that had induced the relatives of the deceased thus to resist his last wish. We would simply remark that if the laws of every civilized country provide that a due respect should be paid to every will which is well conceived and expressed, this duty becomes more imperative when the testator is a person worthy of the highest veneration, as well for his great actions as for his noble aspirations.

It ought to be said that Garibaldi, by the will in question, meant to strengthen in the minds of our people a great philosophical principle, violently opposed as it may be by the enemies of all civil progress, namely, that fire is the surest purifier of the remains of those we mourn, inasmuch as it gives to the elements which compose it the primitive conditions of all future organism. This principle, which was revealed to a few ancient philosophers by a happy intuition, is plainly demonstrated at the present time by strong arguments resting upon facts physical, chemical, and biological of modern science.

The vote passed at the last Congress at Modena by the delegates from the Italian Societies for Cremation is wise and praiseworthy in all its bearings. By this vote the Congress has expressed the desire that "on the occasion of the first anniversary of the death of the great Captain his body should be burned at Caprera." At the same time the Congress requested all Societies for Cremation to agitate this question in their respective localities, so that all citizens may be led to ask of the government and of the family of Garibaldi exact fulfillment of the will of the General.

The Committee of the Italian League of the Societies for Cremation therefore to-day feels it an imperative duty to appeal in the most urgent and solemn manner to sentiments of humanity of the family of Garibaldi and the wisdom of the government for the fulfillment of the last will and testament of the General, and also of the wishes expressed by the first Congress of the Italian Societies for Cremation.

In acting thus Italy will have accomplished a truly sacred and memorable act, while it is also in harmony with the fundamental principles of right, of morality, and of science.

PROF. G. CANTONI, *Senator*.

DR. G. PINI, *Secretary*.

To those to whom, like ourselves, cremation is merely a neater, more expeditious, more agreeable mode of resolving the bodily remains into the original elements, and not necessarily a more prompt or sanitary way of disposing of the dead, such extravagance of language must seem serio-comic or pathetic according as the humorous or sympathetic predominates in the composition. Certainly in this country, and we believe scarcely less in older and more populous communities, it will be a long time before cremation becomes a burning question in other than a strictly literal sense.

In France the opportunity of which the cremationists availed themselves to ride their pet hobby was, as has been said, the outbreak of the cholera epidemic in Egypt. There, too, is a society for the propagation of cremation, with an active president. It seems the Municipal Council of Paris has upon several occasions memorialized the French government in favor of a law to authorize optional cremation, the last time so lately as last June. A deaf ear having been turned to these petitions, the council, immediately upon the breaking out of cholera in Egypt, requested the Prefect of the Seine to take any necessary steps with the government that the city of Paris might be authorized to construct crematory apparatus in each

of the three great cemeteries of the city, to be used only in case of an epidemic. This request was supported by one to the same effect from the President of the Society for Cremation to the Prefect of Police, in the expression of which the president informs the prefect, among other things, that "below the surface of the soil as well as above it the accumulation of dead bodies is the source of pestilential emanations against which cremation alone is capable of protecting the public health in times of epidemics in the large cities."

The Council of Public Health of the Seine, to whom this request was referred, encouraged by an adverse report of M. Brouardel, voted almost unanimously against granting it. The adverse report was based upon the impossibility of dealing with sufficient promptness with the large number of the dead resulting from an epidemic by any process of incineration, and upon the objection from the medico-legal point of view—the opportunity for poisoning with impunity being peculiarly tempting during periods of epidemics. M. Brouardel bases his calculations as to the number of bodies which can be daily incinerated by a limited number of furnaces upon the time required for cremation by the Gorini furnace, which is four hours. With the Siemens furnace, however, only one hour is required, and the process is much less expensive. With half a dozen Siemens furnaces one hundred and twenty bodies, at least, could probably be incinerated in the twenty-four hours. The objections from the medico-legal point of view would be more difficult to meet, at any rate in times of epidemics. Neither a preliminary autopsy, the preservation of necessary organs for subsequent examination, nor the appointment of officers to verify deaths, being practical measures under such conditions.

We suspect the agitation of cremation in countries like France and Italy goes hand in hand with a certain radicalism and hatred of the church, otherwise it is somewhat difficult to account for the extreme zeal of these societies. The Roman Catholic Church expresses a holy horror of the process. If, without going quite so far as Sir Henry Thompson and advocating cremation upon the utilitarian ground of the fitness of the ashes of our departed friends for fertilizing purposes, its functionaries could, with the enlightened Bishop of Manchester, "dissociate the resurrection from physical conditions," and teach "that it would be no more impossible for God to raise up a body at the resurrection, if needs be, out of elementary particles which had been liberated by the burning than it would be to raise up a body from dust, and from the element of bodies which had passed into the structure of worms," we suspect that there would be less interest in cremation and in societies for its propagation, in some quarters.

Now that we have in the Siemens furnace, as in operation at Gotha in Germany, a very cheap, expeditious, cleanly, and perfectly hygienic process for disposing of the dead, it seems a pity that those who prefer cremation should not be allowed the privilege; but it scarcely seems necessary to proselytize very eagerly

about it, for there is still ground enough for those who prefer burial, and cremation, no more than female suffrage or total abstinence from alcohol, is the one thing needed to rescue society from all its woes.

AMBULANCE SERVICE.

We have heard much of late years of ambulance service in cities. The casualties of our modern life are sufficiently numerous to require organized arrangements to meet them as perfect in their way as are required by an army in the field. The size of the city, or rather the number of inhabitants and the daily number of casualties, must determine the ambulance requirements.

New York possesses, probably, the most perfect ambulance system of any city of the world. Each hospital possesses one or more ambulances, Bellevue has eight, which may be summoned at any hour of day or night, to attend to any accident within the particular district of each hospital. Both the fire and police telegraphs may be used to summon an ambulance and the accompanying surgeon. The ambulances also answer a general fire alarm, and use many of the arrangements adopted by modern fire departments to facilitate a speedy departure after the summons. The perfection to which the arrangements have been carried has excited very wide attention, and a halo of romance has been thrown about this service by magazine writers. Whether a system which allows any member of the police patrol to summon the ambulance is liable to abuse is a matter on which the public generally has never been informed. It must certainly allow an occasional impostor to feign a fit and force himself upon the attention of hospital authorities; but if it is so, the great good accomplished by so beneficent a system ought not for a moment to suffer. The necessity of organized ambulance corps is felt in other cities, and such a service has recently been inaugurated in Philadelphia. Dr. De Forest Willard, of the latter city, delivered an exceedingly interesting address upon the subject in April last, which has just reached us. In addition to much interesting and instructive information in regard to the construction of ambulance wagons and the transportation of sick and wounded, it contains a résumé of the service in other cities. In no other city of this country is there any approach to the perfection of the New York service. Generally the service is under the control either of the police or the health authorities. Of Boston Dr. Willard gives the following account:—

"In Boston there are three ambulances, one under the direction of the City Hospital, two controlled by the Board of Police Commissioners. The hospital ambulance is stationed at the City Hospital, the others, one at the north end, the other at the south end, of the city. These are used only to convey the wounded to the hospital, and are accompanied by a surgeon. They carry from five to six hundred per year to the institutions, and monthly reports are rendered to the superintendent. At the Massachusetts General Hos-

pital, an ambulance, with surgeon, will be despatched upon notice from physician, police, or other responsible source."

Such a showing is not inferior to the majority of American cities, but a little inquiry has convinced us that it was by no means a full account of the ambulance force of the city. Beside the two police ambulances at Stations 1 and 4 (Hanover and La-Grange Streets) there is a third, originally intended to be located in East Boston, which has never yet been assigned to its position, but which was some time ago completed, and is now ready for use whenever the necessity for it seems apparent. The vehicle, also, which was used at the City Hospital before it possessed the complete ambulance now in use is still in possession of the hospital, and does service as a light wagon for market and other purposes. It is almost always available in case of sudden emergency which require an extra large service.

The Marine Hospital has an ambulance which transports its patients to and from the hospital, and should be considered in enumerating the ambulances of the city. The Board of Health have also under their control at the Small-Pox Hospital an ambulance of ingenious and peculiar construction for the removal of small-pox patients. The hospital ambulance is not ordinarily accompanied by a surgeon, but by one of the attendants from the wards skilled in handling the sick.

The necessities for a complete service for the relief of wounded persons in Philadelphia,—and the same necessities exist to a greater or less degree in other cities, according to Dr. Willard,—are,—

(1.) Material for comfortable and speedy transportation, stretchers, wheeled litters, and horse-ambulances, to be provided by the city, and to be stationed, the former at the station-houses and depots, the latter at the hospitals.

(2.) Skilled medical care to be provided by the arrival in a few minutes of a surgeon with every means of appliance for the emergency, and a continuance of this care until the patient is safely landed in a place of rest, either at his home or in a hospital.

(3.) A thorough coöperation between the police and the hospitals.

(4.) Quick means of communication by special telephones between the police stations, hospitals, and offices of the visiting surgeons.

(5.) The strengthening of the financial condition of the hospitals by assistance from the municipal authorities and by private individuals. The former can be done by a yearly appropriation, as is the case in other cities, for the maintenance of ambulance horse, driver, and surgeon; the latter by the endowment by firms and by individuals of a hospital bed in which they can place their injured employees.

—The *Lancet* does not believe in the anti-hygienic effect of wood pavements. It says they have no more to do with the "serious affections of the eyes and lungs" ascribed to them by a sanitary journal than "Tenderden steeple has with Goodwin sauds."

MEDICAL NOTES.

—The Medical School of Harvard University celebrates the one hundredth anniversary of its establishment, and dedicates its new building on October 17th. The programme for the occasion is as follows:—

I. Address by the President of the University. Oration by Emeritus Professor Oliver Wendell Holmes. Presentation of a portrait of Professor Holmes, and a bust of Prof. Henry J. Bigelow.

II. Prayer by Rev. A. P. Peabody, D. D. Dedication of the new building, Boylston Street, to the purposes of medical instruction. Reception of subscribers to the building fund and invited guests by the Medical Faculty. Exhibition of the building.

—Dr. Fischer, of Trieste, has, according to *New Remedies*, made experiments with cellulose as a dressing for wounds, and has found it, when moistened with warm water or some medicated solution, and afterwards covered with an impervious fabric, to be a most excellent application in all cases where heat and moisture appear to be indicated. Its chief advantages are: (1.) It is absolutely free from substances capable of exciting putrefaction. (2.) It has a very low specific gravity. (3.) It produces neither eczema nor erythema upon the epidermis. (4.) It retains moisture and heat perfectly for more than twenty-four hours. (5.) It never adheres to granulating wounds on the surface of the skin. (6.) It adapts itself perfectly to the outline of the place of application. (7.) It is much cheaper than other materials heretofore used for similar purposes. Dr. Fischer has used, so far, only plain water or weak solution of carbolic acid or iodoform in the case of suppurating buboes, and has obtained uniformly satisfactory results.

—An extraordinary incident, in which an athlete showed great presence of mind and unusual muscular strength, happened at Cranachan Farm, near Dundee, the other day, and is reported in an English contemporary. Mr. Archibald Macdonald, one of five brothers who occupy the farm, was going over his land accompanied by the shepherd, and, when they were passing through a field in which cattle were grazing, a bull gave them chase. The shepherd ran, and left his master to his fate. Mr. Macdonald could not run, he having suffered much from rheumatism, and being now obliged to use crutches. The bull approached, and began to attack him, he doing his best to keep him at bay with the aid of his crutches. As good luck would have it, Mr. John Macdonald, an elder brother, bearing cries, ran to the rescue. In his hurry he forgot to bring any instrument with him with which to fell the brute; but it occurred to him that if he caught the bull by the horns he might keep him from doing more mischief till help arrived. Seizing the enraged animal by the horns, and using them as levers, with one supreme effort he gave a sudden twist to the head, dislocating the neck by his jerk, and, in a moment, the bull fell helpless at his feet. Mr. John Macdonald was at one time champion athlete of Scotland.

—The *British Medical Journal* warns the public that clothes which are quite new are especially liable,

under certain circumstances, which it fears are comparatively common and frequent, to be impregnated with the specific germs of zymotic disorders. It is a trade custom, which is especially in vogue in large towns amongst tailors, dressmakers, and others who make clothes, to employ largely the services of outdoor assistants. Under this system materials are "given out" at shops to outworkers, who take the fabrics home and there make them up into garments, which are finished, carried to the shop, and distributed to the customers. Such outworkers are usually poor persons, and they often live amid surroundings which practically make zymotic disease a perpetual circumstance of their existence. It can be no marvel that these poor assistants of tailors and dressmakers, with the payment of their toil often cut down to the lowest limit, and driven by the stress of poverty to work even when ill, sometimes infect or allow to be infected, through ignorance or recklessness, the materials on which they work. Scarlet fever and small-pox are the zymotic diseases which are especially apt to be spread under the conditions in question. This is so for the two following reasons: the subjects of scarlet fever and small-pox are very commonly able to do comparatively light work, such as needle-work, especially in their own homes, and even upon their beds, during a considerable portion of the infectious stages of their illness; and the emanations from the subjects of scarlet fever and small-pox, which are conspicuously, if not solely, contagious, namely, the desquamated epidermis in the case of scarlet fever, and the desiccated crusts in the case of small-pox, are *materies morbi*, which, relatively to the contagia of other zymotics, are very substantial, and especially liable to be caught and kept in the meshes of textile fabrics. The circumstances which cause this exposure in England are not altogether wanting here, though we believe that it is more common with us for the clothes to be made in the building where they are cut.

—We notice that at the recent opening of the autumn session of a medical college — so called — the President of the Faculty informed his audience that it was the only medical institution founded in the Christian religion, as all the members of the Faculty are required to be Christians, and the establishment of a pulpit is under consideration!

NEW YORK.

—A report on typhoid fever has been made to the Board of Health by Dr. Day, sanitary superintendent, in which he states that special attention has lately been given to this subject under the direction of the sanitary committee. All cases of the disease have been carefully investigated, and the families in which they occurred instructed in the use of disinfectants; while subsequent visits of inspection have been made. Typhoid fever has been slightly on the increase all through the year. Thus, in the first quarter of 1883 there were reported 120 cases, against 101 during the first quarter of 1882; and in the second quarter of 1883 83 cases were reported, against 67 cases during the corresponding period of 1882. In July of

the present year, however, there was a marked increase in the number of cases, the number reported being 98, against 40 during July, 1882; while in August the increase was still more noticeable, the number of cases being 244, against 96 during August, 1882. The report then continues as follows: "We must expect that this increase will continue as cold weather sets in and the city fills up with people from the country. A map of the cases, so far as prepared, does not show that the disease is confined to any particular locality, but is rather distributed generally over the city among those who do not avail themselves of early medical advice. The particular object of this communication is to call the attention of the Board to the neglect of proper disinfection in typhoid fever, as is shown in the reports of our inspectors. In several instances already, where there were no sanitary defects to account for it, five or six cases have occurred in one family. In these instances it has been found that the undisinfected excreta of the patients have been left for hours in the room where the sick and well have been together. . . . The vital point in the sanitary treatment of typhoid fever is the efficient disinfection of the clothing, bedding, and discharges of the patient, and whatever the Board can do to impress this upon the medical profession of the city, particularly at this time, will be an important factor in controlling the disease during the approaching winter."

In view of the present prevalence of the disease the Board of Health has issued an address to the public, which concludes as follows: "In the light of these vital needs the Board appeals to the citizens of New York to carry out in their own houses the advice contained in the report, and either destroy or thoroughly purify every article of clothing which has been in contact with typhoid fever patients, and empty at once all vessels used by them, and disinfect immediately after using. The Health Commissioners ask physicians and nurses to lose no opportunity to instruct the families of patients in these simple principles of health and protection of life, with a full sense of the responsibility resting on those who are charged with the personal care of the patients."

—At the last meeting of the Board of Health, Sanitary Superintendent Day presented a summary of the work performed by the summer auxiliary corps of visiting physicians. During their term of service they visited 43,915 houses, containing 198,932 families, prescribed for 6601 patients, and distributed 24,631 health circulars and 5195 tickets for the excursions of the Floating Hospital of St. John's Guild. Of the patients treated 3264 suffered from diarrhoeal diseases, 986 from diseases of the respiratory organs, 285 from contagious diseases, and 2086 from miscellaneous diseases.

—During the past summer the Floating Hospital of St. John's Guild made thirty-two regular excursions, on which 19,564 children and mothers were carried, and twelve extra excursions, on which 9625 were carried; making a total of 29,189 persons who were given the benefit of sea air. The Sea-Side Nursery of the Guild at Cedar Grove, Staten Island,

was also filled to its utmost capacity during the greater part of the summer.

— A farmer in Essex County has had a rather uncomfortable and, it is to be hoped, exceptional experience with some "fresh air fund" boys sent from New York during the summer. He had five of them at his house, and, according to the *Maloune Palladium*, the first day after their arrival they hung his large pet Newfoundland dog to an apple tree in the morning, and in the afternoon placed his light wagon across the railroad track, where it was totally demolished by a train.

Miscellany.

THE TREATMENT OF PELVIC PERITONITIS.

DR. GOODELL, in a clinical lecture on a case of this disease,¹ thus describes his treatment. He advises to lay aside all small doses, and treat the case heroically.

"In the first place give as much morphia as is necessary to relieve the pain, if you choose a hypodermic injection of morphia at first, but I prefer the use of opium by the rectum. I never give less than one grain of the aqueous extract of opium. It is a very good plan to add belladonna by the rectum, but do not put it in the same suppository as the opium. Belladonna is very good for the urinary tenesmus, and it also has an effect in lessening the inflammation. You have to push the opium, but cannot push the belladonna. I also give large doses of quinine, giving in bad cases ten grains every four hours until the patient is completely cinchonized and is deaf. I next put a large poultice of flaxseed or corn meal over the abdomen. If this is covered with rubber or a piece of brown paper greased with lard it will keep moist and warm for twelve or twenty-four hours, for the rubber or greased paper retains the heat, and the temperature in these cases is always elevated, running up to 103° F. or 104° F. in the evening, and down to 101° F. in the morning.

"After you have passed the brunt of the disease you must begin to use blisters. In this case the worst is passed, but her temperature is, I am sure, not under 100° F. I shall blister her. How shall we blister? Here is a woman who has strangury to a certain extent, and you do not wish to apply a blister that is going to increase the trouble. I always use the caustharidal collodion. I shall paint a blister in this instance three by four inches, putting on three or four layers, and then at once put over this a poultice. This is an almost painless way of raising a blister. I have never seen it produce strangury.

"Now, gentlemen, in a case of frank inflammation, such as that produced by a sound, where there is nothing of a concealed character, this treatment will subdue it, but if the peritonitis is produced by sponge tents you have a bad case to treat.

"I am sometimes called in consultation to a case of peritonitis by some of my students, and they tell me, 'I am giving quinine just as you direct us. I am giving two grains every three or four hours.' That is nothing at all. You should never give less than five grains.

¹ Medical Times, August 25th.

"You will find certain nervous symptoms present. The woman will be weak and trembling, ready to burst out crying. In such cases I very often give large doses of the bromides, from sixty to one hundred grains in the twenty-four hours.

"If you treat your cases in this heroic way, you will, in the great majority, cure them at the very beginning of the disease."

YELLOW FEVER AT GUAYMAS.

YELLOW FEVER has broken out with much virulence at the port of Guaymas on the Gulf of California. The mortality has been considerable in proportion to the population, and many of the more well-to-do have fled the town.

Guaymas is the terminus of the Sonora Railway, and thus of the Atchison, Topeka, and Santa Fé system.

MEDICAL EXAMINERS IN RHODE ISLAND.

THE proposed act in Rhode Island for substituting medical examiners in place of the old system of coroners, still obtaining there, was brought up for discussion at the last quarterly meeting of the Rhode Island Medical Society upon presentation of the report of the committee to which the subject had been referred. A report of the meeting appears on another page of this issue of the JOURNAL. No action was taken, and a further consideration of the question is anticipated at the next meeting of the Society.

We commented editorially upon some of the provisions of the act last week, and are pleased to learn that the Society will carefully consider all the details of the proposed law before giving its valuable support to it in the Legislature.

PULMONARY COMPLICATIONS OF ERYTHEMA NODOSUM.

PROF. GERMAIN SÉE, in a clinical lecture on Erythema Nodosum and the Pleuro-pulmonary Affections which sometimes accompany it (*Progrès Médical*, April 14 and 21, 1883, and *Practitioner*, August, 1883), comes to the following conclusions: (1) that erythema nodosum is a specific fever analogous to the exanthemata, and not a cutaneous manifestation of rheumatism; (2) that the affection, which is usually benign, may, like the exanthemata, be complicated with accidental disorders of the respiratory organs; (3) that pleurisy is the commonest complication, not unfrequently accompanied with broncho-pneumonia; (4) that this pleurisy seems in general to present no peculiar characters; (5) that in a fatal case the characters were the development of the pleurisy in isolated and distinct patches, the unusual thickness and abundance of the fibrinous exudation, and the small amount of fluid effused; (6) that the prognosis of the pulmonary disorder, like that of the primary affection, is favorable, though two cases occurred in which they led to a fatal result; (7) that the pleuro-pulmonary complications are not rheumatismal in origin any more than the primary erythema; but that they are directly referable to the specific principle or virus of the disease.

REPORTED MORTALITY FOR THE WEEK ENDING SEPTEMBER 15, 1883.

Deaths reported 2635 (no reports from New Orleans and District of Columbia); under five years of age, 1178; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 711, diarrhoeal diseases 334, consumption 293, lung diseases 177, diphtheria and croup 145, typhoid fever 92, scarlet fever 61, malarial fevers 28, cerebro-spinal meningitis 16, whooping-cough 17, puerperal fever 10, measles nine, erysipelas seven, small-pox two. From *scarlet fever*, Baltimore 12, New York 11, Philadelphia 10, Brooklyn seven, Chicago and St. Louis five each, Pittsburg and Buffalo three each, Boston two, Cincinnati, Fall River, and Somerville one each. From *malarial fevers*, New York eight, Brooklyn seven, St. Louis five, Chicago and Baltimore three each, Charleston and Nashville one each. From *whooping-cough*, New York seven, Chicago three, St. Louis and Cincinnati two each, Boston, Baltimore, and Milwaukee one each. From *cerebro-spinal meningitis*, Philadelphia four, Chicago, Milwaukee, and Springfield two each, Boston, Baltimore, Cincinnati, and Lowell one each. From *puerperal fever*, Brooklyn three, Boston two, Philadelphia, St. Louis, Baltimore, Buffalo, and Providence one each. From *measles*, New York five, Boston, St. Louis, Baltimore, and Pittsburg one each. From *erysipelas*, Brooklyn two, New York, Philadelphia, Buffalo, Charleston, and Lynn one each. From *small-pox*, Philadelphia two.

In 38 cities and towns of Massachusetts, with an estimated population of 1,083,823 (estimated population of the State 1,922,530), the total death-rate for the week was 22.45 against 21.21 and 22.96 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending September

1st, the death-rate was 19.8. Deaths reported 3278: diarrhoeal diseases 407, acute diseases of the respiratory organs (London) 148, scarlet fever 110, measles 95, fever 56, whooping-cough 53, diphtheria 24, small-pox (London four, Birmingham two, Sunderland one) seven. The death-rates ranged from 13.1 in Halifax to 29 in Newcastle-on-Tyne; Bristol 15; London 17; Bradford 18.9; Sunderland 19.4; Leeds 20.1; Nottingham 21.2; Birmingham 21.3; Liverpool 24.8; Sheffield 25.3; Brighton 26.7; Leicester 27; Manchester 28.3. In Edinburgh 18.1; Glasgow 27; Dublin 23.4.

For the week ending August 25th, in 171 German cities and towns, with an estimated population of 8,610,255, the death-rate was 24.8. Deaths reported 4104; under five years of age, 2257; consumption 449, diarrhoeal diseases 369, lung diseases 257, diphtheria and croup 129, typhoid fever 68, scarlet fever 58, whooping-cough 52, measles and r6theln 49, puerperal fever 20, small-pox (Breslau and Bremen one each) two. The death-rates ranged from 8.8 in Kiel to 37.5 in Munich; K6nigsberg 30.4; Breslau 35.8; Dresden 26.5; Berlin 28; Leipzig 28.9; Hamburg 21.4; Cologne 21.3; Frankfort 22.1; Strasburg 22.5.

For the week ending September 1st, in the Swiss towns, there were 32 deaths from consumption diarrhoeal diseases 27, lung diseases nine, diphtheria and croup five, whooping-cough three, puerperal fever three, typhoid fever two, measles one, small-pox one. The death-rates were at Geneva 8.2, Zurich 10, Basle 19.9; Berne 23.7.

The meteorological record for the week ending September 15th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM SEPTEMBER 14, 1883, TO SEPTEMBER 21, 1883.

CAMPBELL, JOHN, lieutenant-colonel and surgeon, medical director Department of the South. Granted leave of absence for fifteen days. Paragraph 2, S. O. 94, Department of the South, September 13, 1883.

ALEXANDER, CHARLES T., major and surgeon. On being relieved from duty at the United States Military Academy, October 1, 1883, to report in person to the commanding general, Department of the Missouri, for assignment to duty. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

ALEXANDER, CHARLES T., major and surgeon. Granted leave of absence for four months from October 1, 1883. Paragraph 1, S. O. 213, A. G. O., September 17, 1883.

GIBSON, JOSEPH R., major and surgeon. Relieved from duty in the Department of the East, October 1, 1883, and to report by letter to the commanding general, Department of the South, for assignment to duty. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

HORTON, SAMUEL M., major and surgeon. Relieved from duty in the Department of the Platte, October 1, 1883, and to report in person to the commanding general, Department of the Missouri, for assignment to duty. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

MEACHAM, FRANK, major and surgeon. Relieved from duty in the Department of the East, October 1, 1883, and to report in person to the commanding general, Department of the Platte, for assignment to duty. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

SMITH, ANDREW K., major and surgeon. Relieved from duty at Willet's Point, New York, October 1, 1883, and assigned to duty at the United States Military Academy, West Point, New York. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

TAYLOR, MORSE K., major and surgeon. Relieved from duty in the Department of the East, October 1, 1883, and to report in person to the commanding general, Department of the Missouri, for assignment to duty. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

WOLVERTON, WILLIAM D., major and surgeon. Relieved from duty in the Department of Dakota, October 1, 1883, and to report in person to the commanding general, Department of the East, for assignment to duty. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

APPEL, DANIEL M., captain and assistant surgeon. Relieved from duty in the Department of the Missouri, October 1, 1883, and to report in person to the commanding general, Department of the East, for assignment to duty. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

BARTHOLOMEW, JOHN H., captain and assistant surgeon. Station changed from Fort Lapwai, I. T., to Vancouver Barracks, W. T. Paragraph 2, S. O. 123, Department of the Columbia, September 6, 1883.

MERRILL, JAMES C., captain and assistant surgeon. Relieved from duty in the Department of Dakota, October 1, 1883, and to report in person to the commanding general, Department

of the East, for assignment to duty. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

MAUS, LOUIS M., captain and assistant surgeon. Relieved from duty in the Department of the Missouri, October 1, 1883, and to report in person to the commanding general, Department of Dakota, for assignment to duty. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

MUNN, CURTIS E., captain and assistant surgeon. Relieved from duty in the Department of the Missouri, October 1, 1883, and to report in person to the commanding general, Department of the East, for assignment to duty. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

PATZKI, JULIUS H., captain and assistant surgeon. Relieved from duty in the Department of the South, October 1, 1883, and to report in person to the commanding general, Department of the East, for assignment to duty. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

PRICE, CURTIS E., captain and assistant surgeon. Relieved from duty in the Department of the East, October 1, 1883, and to report in person to the commanding general, Department of Dakota, for assignment to duty. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING WEEK ENDING SEPTEMBER 22, 1883.

BRYAN, J. H., passed assistant surgeon, detached from the U. S. S. Miantonomoh, and ordered to the Museum of Hygiene, Washington, D. C.

MACRUDER, A. F., passed assistant surgeon, detached from duty at Villefranche, France, and granted six months' leave, with permission to remain abroad during that period.

HALL, C. H. H., passed assistant surgeon, to be detached from the U. S. S. Ranger on reporting of his relief, and wait orders.

NEILSON, J. L., surgeon, detached from the Receiving Ship Franklin, at Norfolk, Va., and ordered to the U. S. S. Ranger.

CORWIN, WILLIAM A., surgeon, ordered to the Receiving Ship Franklin, Norfolk, Va.

WHITING, ROBERT, passed assistant surgeon, detached from the Receiving Ship Wabash, at Boston, and ordered to the Naval Hospital, Norfolk, Va.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The meetings of the Section for Clinical Medicine, Pathology, and Hygiene for the coming year will take place October 10th, and on the second Wednesday of each month thereafter during the winter. Members will please send the titles of any papers or communications they may desire to present at as early a date as possible to

ALBERT N. BLODGETT, Secretary,
86 Boylston Street, Boston.

Lectures.

CLINICAL LECTURE ON FAILURE OF SEXUAL DEVELOPMENT;¹

DELIVERED AT THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

BY PROF. T. GAILLARD THOMAS, M. D.

GENTLEMEN,—The little girl whom I present to you to-day is a clinical lecture in herself. Her name is Rachel W., and her parents are Polish Jews. She is eighteen years of age, and yet, to look at her, you would never imagine that she was anything more than a child of twelve. Physically she is, indeed, a girl of twelve; but chronologically she is a young woman of eighteen. The history, as derived from her mother and herself, is a very brief one: She is all the time sick, she says; complaining of weakness and more or less cough, and of pains in the head, back, chest, limbs, and lower part of the abdomen. In addition, her mother informs me that she has never in her life shown any sign of menstruation. It is true that, in answer to a leading question, she says that at a certain part of every month the pains mentioned are aggravated; but this statement must, I think, be received with some degree of allowance. When the girl speaks you cannot but be struck by the peculiar character of her voice. It is that of a boy of eighteen, whose voice has just undergone the change incident to the age of puberty, and is certainly a much more man-like voice than that of her mother.

These, then, are the facts of the case. The inference which we draw from them is, that that remarkable change which ordinarily takes place at puberty has not in this instance occurred; a conclusion which is confirmed by the physical examination, of which I will presently speak to you. What the special reason for the non-appearance of this change is we cannot say, though the ganglionic nervous system is probably at fault. At the age of puberty, as you know, the uterus in ordinary cases rapidly grows to three times its former size, and the ovaries also become much more fully developed. Ovulation then takes place, and when menstruation has once commenced, the uterus becomes still further enlarged. In a certain number of cases, such as you will meet from time to time in your practice, these changes do not take place. In the present instance the condition of the patient approaches that of cretinism, so commonly met with in some parts of Switzerland, except in regard to mental capacity, as this girl is perfectly intelligent. If nothing is done in the way of treatment, and possibly in spite of this, should it be attempted, she will be a little old woman at forty, no larger than she is now. Here there has been an abnormal development, so that the voice is that of a man. The mammae are also like those of a man, and her form entirely lacks that rotundity and size which we ought to find at her age. The condition of this patient is, indeed, that of a woman from whom the ovaries had been removed before the age of puberty. There are, however, a few rare exceptions, in which the individual, while having the vagina, uterus, and ovaries perfectly developed, is yet altogether like a man in other respects.

I will now show you upon the blackboard what the

vaginal examination revealed here. I found that the hymen offered no obstruction whatever, as one would naturally expect in such a case, and, passing my finger up the small vagina, I found at its upper extremity an acorn-like uterus, such as I now depict for you. By means of conjoined manipulation I then endeavored to determine the size and position of the ovaries, but found this quite impossible. Nothing is to be inferred from this, however, as it is often the case that the ovaries when of normal size, and even when somewhat enlarged, cannot be found at all by the examiner. You should always receive with considerable allowance the statement of any one who says he can map out the ovaries with perfect ease. He may imagine that he does this; but the chances are that he is quite mistaken about the matter. In certain favorable subjects the ovaries, when of normal size, can be thus mapped out; but in a very large number of cases this is utterly impossible. Here, then, we have an infantile, undeveloped uterus, with probably the same condition of the ovaries.

What is the prognosis in a case like this? Some fifteen or twenty years ago the treatment of such cases received a great deal of attention, and the gynecologists reported quite a number of successful results. I myself was one of those who did so, and who felt sanguine of the same good results in other cases. Since then, I must confess, I have lost a good deal of faith in regard to the matter, for I have found by experience that it is only in a very limited number of cases that treatment is at all satisfactory. While, however, I should be by no means hopeful in the case of this girl, I certainly think that she ought to have the benefit of a special course of treatment. It would be easy enough to say that as nature had failed to do her part, there would be no use in trying to accomplish anything here. But instead of taking such a hopeless view of the case, which would condemn the girl to a life with very little happiness in it, I would advise that at all events the attempt should be made to spur on nature to carry on the development which for some reason she has hitherto neglected in this case. If at the end of three months of persevering and systematic effort no progress had been made, I should then think it useless to go on with any further treatment.

I shall, therefore, endeavor to persuade the mother to let her daughter enter my service at the Woman's Hospital, and I will now give you an outline of the plan of treatment that will be adopted in case she gives her consent. In the first place you will understand that if by any means, by directing nutrition to the uterus, we can enlarge the organ, a considerable amount of good will be accomplished; and if, in addition, the ovaries can be excited by reflex irritation, there will be some ground of hope for a successful result. In my private hospital there is at present a young girl of seventeen who has improved in the most wonderful manner under treatment, and in whom the menstrual flow can now be brought on regularly every month. The plan of treatment that I pursue in such cases is as follows: I begin by inserting into the uterine canal a very small sea-tangle tent, which I keep in position by tamponing the vagina. This is to be removed in twenty-four hours, and in two or three days a slightly larger tent is put in. After a time two or three small tents may be used together, and in this way we can really make the uterus grow by producing an afflux of blood to the organ. It is, to be sure, a very clumsy way of

¹ Reported for the Boston Medical and Surgical Journal.

accomplishing this; but as it is the only way that I know of, I am content to practice it. As time goes on we can use larger tents, and if we really succeed in increasing the size of the uterus somewhat, a glass stem should be introduced into the cavity and supported by a cup pessary. This stem should be worn both day and night, but should be taken out once in every three or four days. At the same time means should be directed to the improvement of the general system. Highly nutritious food is of the first importance, and the patient should have not three, but six, meals a day. This is what the young lady of whom I have just spoken is getting. That is, she has her three regular meals, and, in addition, a tablespoonful of malt extract in a tumbler of milk midway between breakfast and luncheon, between luncheon and dinner, and when she goes to bed at night. Such patients rarely have an appetite, and they must really be forced to eat, although not exactly in the way in which fowls in course of artificial fattening in Europe are forced. Some of you may have seen at the *jardin d'Acclimatation* in Paris the ingenious system of M. Martin, by which fowls, in consequence of forced alimentation given regularly every three hours, are doubled in weight in eighteen days; while in a barn-yard they might not fatten in six months. In the matter of feeding such patients it is almost always necessary to combat the will, and especially in regard to the matter of milk, which at first they all say that they cannot possibly take. Girls of this class are always anæmic, and require a large amount of nourishment. Look at the face of the one now before you, and see how pallid it is. Very likely she takes a cup of tea and some bread for her breakfast, some salt meat or fish with potatoes for her dinner, and tea and bread again at night. If she should enter the hospital special attention would be paid to her diet, and I think it would be found that she would gain at the rate of two or two and a half pounds a week. But, besides, it would be necessary to look after the condition of her skin, which now feels more like iced parchment than anything else that I can think of. The impression which it gives one is precisely that of the skin of a man suffering from cirrhosis of the liver. To bring about a healthy condition of the cutaneous surface she would be given three Turkish baths each week, and on the days when she did not have a bath massage would be thoroughly applied by a professional manipulator. In this way the entire skin would be stimulated to action, and passive exercise given to every muscle of the body. In addition, she would be required to exercise with gymnastic apparatus every day after the bath or the massage. In private practice it is, of course, not so easy to carry out such a course of treatment as in a hospital; but it should be imitated as far as possible, and if the mother of the patient is intelligent, all the principal difficulties in the way can be overcome. What, then, have we done so far? In the first place we have improved the blood state of the patient; secondly, we have improved the cutaneous circulation and given tone to the nervous system; and, thirdly, we have to some extent developed the uterus.

We now begin to add something to the treatment, and that is, electricity. The galvanic battery, I think, is the best for the purpose, and a cup electrode should be placed over the cervix uteri while the other electrode is carried to the nape of the neck, and then down along the spine. In the same way an electrode should be placed over the ovaries in succession, so as to stim-

ulate these organs also by direct irritation. It may be that in the course of three months after the commencement of the treatment an erratic hæmorrhage from the uterus will come on, and this is to be regarded as a most encouraging symptom, for it is almost sure to be followed by others. In my private case, as I said, I can now bring on the flow regularly every twenty-eight days, and the young lady is so greatly improved in every way that she and her friends are abundantly satisfied with the result, and she will now soon leave the hospital. She certainly looks like an entirely different person from what she did before the treatment was undertaken. For the present, however, she will each month come to my office three days before the time for the menstrual flow, when by means of a Peaslee uterine sound (which I prefer because it has a very blunt point), covered with rubber with the exception of the last two or three inches, a galvanic current will be applied to the fundus. The ovaries will also be stimulated by the same agent. On the following day, and again on the day when the flow is expected, this application will be repeated. In one case the procedure resulted in pelvic cellulitis; but as this is the only instance out of a very large number of patients in whom I have used this course of treatment, I think there is very little danger of this occurring.

It is very evident that something ought to be done for this girl. It is very easy for the physician to screen his conscience under the shelter of a prescription in such cases; but in every instance of the kind an honest and persevering effort ought certainly to be attempted. If at the end of three months, however, there should not be any indication of ultimate success, it would scarcely be worth while, as I have intimated, to carry the trial any farther. My private case, to which I have so often alluded, has proved a brilliant success; but this, you must understand, is the exception rather than the rule. The first case which attracted special attention to this subject in this city was that of a young lady in high life who, in addition to her other troubles, suffered from epilepsy. A well-known gynecologist undertook her case and succeeded in bringing on the menses; while the epilepsy, greatly to the satisfaction of the patient and her friends, almost entirely disappeared in consequence. Of course, the success achieved in this instance induced many other physicians to adopt the plan of treatment in similar cases. The reason that I do not have the same confidence in it that I did once is, that while in a few cases the method is successful, there are a great many others in which the result is negative. To illustrate how changes take place in medical opinion, I may mention that not longer than ten or twelve years ago sterility was almost universally treated in this city by cutting open the neck of the uterus. You all know the history of the operation which was introduced by Sir James Y. Simpson, of Edinburgh. In only one case, perhaps, out of five hundred, it was successful, and so it gradually fell into disuse, until it is now almost entirely abandoned. It has, indeed, been given up more than I think it really ought to be, as there are a certain number of cases in which it seems to be legitimately called for. This is an important case, as it is a type of a class that you will meet with occasionally in practice, and I have dwelt upon it at considerable length for the reason that I may not have the opportunity of presenting another similar one during the course, as such cases are by no means very common.

If the patient will go in the Woman's Hospital she will be given the benefit of a systematic course of treatment such as I have described, and I will promise to report the progress of the case to you at least once a month while she remains. It is very doubtful, however, whether she will consent to enter the hospital, as persons of her race are apt to be strongly prejudiced against such institutions, and, indeed, against accepting charity of any kind. While speaking of her race, I may mention that it is very rare to find the condition here present in Jewesses, among whom the age of puberty, which, as you know, varies in different races and nations, occurs ordinarily at a very early period.

ON CERTAIN UNRECOGNIZED FORMS OF LEAD-POISONING; AND ON THE POSSIBILITY OF MISTAKING BISMUTH FOR LEAD IN URINE ANALYSES.¹

BY JAMES J. PUTNAM, M. D.

A NUMBER of cases have come to my notice within the past few years in which an examination of the urine has shown the presence of lead, while the symptoms and clinical history were not such as are usually considered characteristic of lead-poisoning, in fact simulated those usually classed as other types of disease. Three of these cases were diffused forms of chronic interstitial myelitis, and two were of the character of cerebral neuroses.

Besides these I have seen two interesting cases with Dr. F. Minot, one presenting some of the symptoms of spastic paraplegia (so-called lateral sclerosis), and the other being a form of diffused poliomyelitis anterior.² In both of them the improvement under iodide potassium seemed to justify the diagnosis, although in the latter case syphilis was recognized as a possible cause of the disease. It is, of course, nothing new to say that lead-poisoning may simulate other diseases, or that any one or all of the classical symptoms may be wanting.

The likeness and unlikeness of some forms of the so-called encephalopathy to progressive paralytic dementia (Monakors and others), to intra-cranial tumor (Byrom Bramwell), to hemiplegia from cerebral hæmorrhage (Raymond and others), has repeatedly been commented upon.

So far as I know, the first case in which lead was supposed to have given rise to symptoms simulating any other form of spinal disease than the poliomyelitis anterior, which some observers believe to underlie the typical atrophic paralysis, is the one, already referred to, which was reported by Dr. F. Minot, of Boston, before the Medical Improvement Society in 1881, and recorded in the Boston Medical and Surgical Journal for the same year.

At the meeting of the Neurological Society in 1882, Dr. Webber read a paper upon the pathology of lead-poisoning, and again brought forward the fact of the relation between lead-poisoning and chronic sclerotic affections of the spinal cord, and reported a case also

resembling in some respects the so-called lateral sclerosis.

Although the idea is not new, therefore, that lead may turn up when least expected, as a cause of obscure forms of disease of the various tissues of the body, yet it is evident that clinical history of the disease is in need of further study. In the first place we require a closer investigation of symptoms in cases where lead is manifestly present; and in the next place it is necessary that a large number of routine examinations of the urine should be made, under due precautions, especially in obscure spinal cases, to ascertain with what frequency lead is liable to be present.

In none of the cases referred to in this paper were blue line on the gums, colic, marked emaciation or discoloration of the skin, characteristic localized atrophic paralysis, or typical cerebral symptoms present, except where the contrary is specified; and the diagnosis was established solely through the examination of the urine, after the administration, for a few days, of iodide potassium.

It is of course not certain that the symptoms observed were really due to the influence of the lead which was found, though from what we know of the liability of lead to set up chronic degenerative inflammations in the various tissues of the body,³ this inference must be admitted to be a fair one.

I shall append at the end of the paper a sketch of the cases referred to, and proceed now to speak of the precautions necessary to a satisfactory examination of the urine for lead.

All the chemical work of the investigation was done in the laboratory of the Harvard Medical College, under the supervision of Prof. E. S. Wood, and the final tests were made by his own hand. The more recent analyses were made by Professor Wood's assistant, Mr. J. W. Perkins, who has been giving especial attention to this subject.

The detection of this metal in the urine is by no means without its difficulties.

Neubaur and Vogel,⁴ writing in 1871, say laconically, that it is sometimes present, but that the analysis is difficult and not always successful. The quantity present, especially when no iodide of potassium is being taken, and also after this drug has been taken uninterruptedly for more than a few days at a time, is, according to M. Pouchet,⁵ not often more than 0.001 to the litre, rising considerably when iodide of potassium is first given, or when its use is suspended for a time and then again resumed. The quantity of urine to be analyzed should therefore be at least one quart, and should be collected during the administration of iodide of potassium, given either for the first time or after an interval of repose.

The liability of the reagents to contain lead is well known. It applies not only to the sulphuric acid and ammonia, but also to the ordinary filtering paper, though not to the so-called Swedish paper.

It is needless to say that Professor Wood was fully alive to these dangers, and took every precaution to avoid them, with what success is shown by the fact that in parallel analyses, which were constantly being made, no lead was found. One additional and important source of possible error suggested itself to him,

⁴ Analyse des Urins.

⁵ Cited in the London Medical Record, November 15, 1880; also by Dr. Hills, Boston Medical and Surgical Journal, vol. cv., p. 125.

however, during the course of this investigation. The final test used for lead depends, namely, on the formation of the yellow iodide of that metal after the addition of iodide of potassium. But the same reagent produces also yellow iodide of bismuth if a compound of the latter metal be present, an important consideration in view of the frequency with which that drug is used in the treatment of common forms of dyspepsia. Bismuth is always given in the form of a basic salt, subnitrate or subcarbonate, and is not absorbed to any great extent, its therapeutic effects being due to its local action upon the mucous membrane of the alimentary canal. A small proportion of this compound is, however, changed into a soluble form and absorbed usually, if not always, and has been found in the urine. How long it continues to pass off in this way has not been shown, but Bergeret and Mayençon¹ found traces of it in the various tissues of a rabbit eight days after the administration of a few grains, and found also traces of it in the human liver and kidneys five days after the administration of one gramme.

For the sake of investigating the point further, I took myself a quantity of the subnitrate of bismuth, varying from thirty grains to forty-five grains, daily for two weeks. At the end of this time, while still taking the drug, my urine (about two quarts) was examined by Mr. Perkins according to the method habitually used in the lead analyses, and a final reaction was obtained which was practically identical with that observed when lead is present. That lead was not present, however, had been shown by a preliminary examination of the urine, which had been prepared for by taking iodide of potassium in the dose of fifteen grains daily for several days. About twenty-four days after ceasing to take the bismuth I again took iodide of potassium, and collected two quarts more of urine during the next two days. This was analyzed, and a trace of bismuth was again found to be present.

It would seem an easy matter to separate lead and bismuth, and a method will no doubt be found for doing so, but the quantities are so small that this is decidedly difficult, and the most reliable way of avoiding this error is to make sure that the patient has taken no bismuth within a considerable period before the examination for lead is made.

Of course the discovery of this source of error throws doubt upon the reality of the assumed lead test in some of my former cases, and I was obliged to omit two interesting ones on that account, and cannot prove that in certain of the others bismuth had not been taken within the time necessary for its elimination. In others, however, among which Dr. Minot's two cases are to be reckoned, it was certain that this had not been the case.

Another source of error of which Dr. Wood has been in the habit of speaking is that if the urine be allowed to undergo alkaline fermentation in bottles made with lead glass, the glass may be decomposed and lead dissolved by the alkali. To avoid this the urine should be slightly acidulated with acetic acid if it is to be kept any length of time.

I append, with Professor Wood's permission, his method of analysis for lead.

The urine is first evaporated to dryness, then fused in a crucible, with the addition of a little pure nitre, till it becomes white. The crucible is then cooled, and

dilute HCl added, hot, to extract the residue after ignition. It is then filtered, and the filtrate treated with ammonia to alkaline reaction to precipitate the phosphates and iron. Sulphide of ammonium is added at the same time, which throws down the sulphide of iron and lead. This is washed three times by decantation with hot water, then water is added, and the whole acidified with HCl, and allowed to stand until the next day. It is then filtered through a small filter, and the residue washed. A little pure (free from iron) nitric acid is then added, drop by drop, by which the sulphide of lead, if present is dissolved, and carried through as nitrate of lead. This is collected in a watch glass, evaporated to dryness, and the final test made (as aforesaid) by the addition of a drop of water and a crystal of iodide of potassium.

The following is a brief outline of the cases to which I have referred:—

CASE I. Woman in middle life. First complaint, "numbness" in all four extremities, with marked debility, severe and progressive anæmia. Six months later, paraparesis of lower extremities, of such a nature as to indicate slight, diffused impairment of all the functions of the spinal cord. Gradual increase of anæmia and paralysis. Death after some months.

No autopsy.

It was impossible to affirm positively whether patient had taken bismuth during course of her illness or not. There had been no typical signs of lead-poisoning, but an examination of the urine had shown the presence of "considerable lead."

CASE II. Man,² fifty-five years of age, captain of police by profession; always robust and well. No syphilis, no exposure to cold. Two months before examination, attack of pain in chest, with slight difficulty in breathing. Soon after, sense of numbness and heaviness in the legs, and for a time progressive difficulty in walking. No atrophy nor material impairment of sensibility, nor any disorder of micturition.

"Considerable lead" was found in the urine after the administration of iodide of potassium. The patient had been in the habit of drinking more or less from a lead-lined tank in his office. Dr. Fuller stated that he had taken no bismuth for several weeks before the examination, and then only a small quantity, perhaps a drachm in all.

The following case was seen by me at the Massachusetts General Hospital in consultation with Dr. B. S. Shaw, who kindly allows me to report it. Although the condition of the hands would in itself have suggested the diagnosis, yet the symptoms referable to the legs are noteworthy, the more so that they resembled (in respect to the exaggerated knee-jerk) some of the cases reported by Drs. Minot and Webber.

CASE III. Patient is a restaurant keeper, fifty-seven years of age. For past year has suffered from severe pain in sacral region, increased by sudden jar; also from excessive constipation, with occasional attacks of diarrhoea, nausea, and vomiting. Recently there has been some difficulty in retaining urine; slight numbness in feet and legs, and impairment of strength in them. There is exaggeration of knee-jerk and plantar reflex; slight tremulousness of hands and tongue; some wasting of interosseous muscles of hands and of thenar muscles; no blue line on gums. Urine contains no albumen, but (after administration of iodide of potassium) "con-

¹ Cited by H. C. Wood, *Therap. Mat. Med. and Toxicol.*, edition of 1874, page 38.

² Seen in consultation with Dr. Fuller, of Charlestown, who kindly allows me to report the case.

siderable lead." Improvement under treatment by iodide of potassium.

The following cases, although not of spinal origin, are certainly not without interest:—

CASE IV. A German lady, rather stout, but not unhealthy in appearance, was seen by me two years ago in consultation with Dr. Ruddick, of South Boston. The symptoms of which she complained were mainly vague dizziness and obscure sensations of discomfort in the head, ringing in the ears, and dyspepsia. The ears were examined by Dr. C. J. Blake, and some middle-ear trouble found, which he succeeded in removing in a measure, with partial relief to the symptoms.

Although the classical symptoms of lead-poisoning were absent I had the urine analyzed, and lead was found. There was no syphilis nor nephritis.

The water which this patient drank ran from the street main to the house through a lead pipe. I asked her to send me a gallon of this water, and this was found on analysis to contain a relatively large quantity of lead, a good deal more than is usually found in Cochituate water under these circumstances. It cannot, unfortunately, be positively asserted that this patient had not been taking bismuth.

Apocryphos of the contamination of water from lead pipes, I will mention a point of practical interest spoken of to me by a plumber with whom I have talked. It is, namely, well known that hot water is more apt to dissolve lead than cold, but it is, I think, not generally realized that this fact makes it objectionable to run hot and cold water-pipes side by side through the house, especially where the latter carry water for drinking purposes. The plumber, Mr. W. H. Greenleaf, assures me that the cold-water pipes under these circumstances are apt to be considerably corroded.

CASE VII. A man, thirty-two years of age, a gas-fitter by trade, came to the Massachusetts General Hospital, Out-Patient Department, in September, 1882, complaining mainly of sense of numbness and pricking of hands and feet, rather worse during the day, but felt also at night, and sometimes remitting altogether. When this "numbness" was severe the legs felt heavy and helpless. He complained also of headache; of attacks of dizziness, without loss of consciousness, recurring every day or two; of twitching of the muscles, mainly left arm and leg; and of a sense of coldness and trembling throughout the entire left side. The hands could be thrown into full extension, even with the fingers spread and extended, but when in this position some trembling was seen, and at a later period a careful electrical examination of the extensor muscles of the fingers showed a marked diminution of reaction to the faradic current. There were no distinct spinal symptoms, unless somewhat delayed micturition at times be such, and the heart and arterial system appeared normal. The complexion was pale and sallow, and the conjunctivæ of yellowish hue. Examination of the gums revealed the presence of a faint "blue line," and examination of the urine after iodide of potassium had been taken for a few days showed the presence of "much lead." Possible partial causes of his condition were syphilis, since he had had a chancre, without secondary symptoms, ten or eleven years before, and abuse of tea, coffee, and tobacco. His improvement under treatment has been very great in all respects, but the urine still contains lead, or did a short time ago.

Generalized tremor of the muscles, without paralysis, is a symptom which, though rather rare, is well recognized,¹ but when so slight as in the following case, and so completely unattended with characteristic symptoms, the difficulties in the way of diagnosis might be considerable.

CASE VIII. An athletic and previously healthy medical student came to me some months ago complaining of very slight trembling of the muscles all over the body, though noticeable to any one else only in the hands with the fingers in extension. No loss of power was discoverable, nor other symptoms of any kind, except some obscure signs of general debility, referable to confinement at work.

As a matter of precaution the urine was examined for lead, and a "considerable quantity" was found.

Subsequently a very careful examination with electricity revealed a diminution of irritability of the extensors of the fingers to the faradic current, though so slight that its presence could hardly be asserted with confidence.

No source for the lead could be discovered.

DIETETICS FOR THE SICK.²

BY CHARLES M. SELTZER, M. D.

IN presenting this paper it is but justice to state that it has been prepared during the leisure of the past week as a substitute for one by another member who was unable to keep his engagement. The subject has been selected more from the hope of eliciting some practical ideas, and a desire to emphasize its importance, than to announce anything new, or to exhibit the best paces of a hobby. Close attention to the methods of our most successful general practitioners convinced me that in dietetics was their stronghold. At the same time there was plainly to be seen a distressing lack of knowledge as to variety of foods, and the preparation of them. In order to find out whether there was a practical remedy for these two great faults, I have gone over a thorough course of preparation of diet for the sick, under the instructions and guidance of Mrs. S. T. Rorer, in whom are combined the practical attributes of cook, chemist, physiologist, and nurse, and I can safely say that if every member of this Society were to do likewise their *armamentarium*, success, and self-satisfaction in the practice of medicine would be increased many fold.

It would be almost an endless task to discuss the literature of this subject. Let us condense the opinions of physiologists, chemists, hygienists, and all others in authority, by stating that food is divided into nitrogenous or albuminous, hydro-carbous or starch, sugar, and fats, and mineral or the various salts of the alkalies. Of these the nitrogenous and minerals are the building materials, and the hydro-carbous are the heat and force producers. Food may also be classified into liquid, semi-solid, and solid, and as the sum total of digestion is a matter of absorption and assimilation, it follows that the more liquid or dissolvable food is the more readily will it be absorbed; hence this is the form to be chosen when it is desirable to obtain nourishment at the least possible expense of organic action.

¹ Vide Axenfeld and Wuchard, l. c., page 663.

² Read before the Philadelphia County Medical Society, September 12, 1883.

There are also conditions in which bulk and solidity are necessary, and here we select the semi-solid or solid food, or even indigestible matter.

Nitrogenous food, in its natural combination with mineral matters, is mostly made absorbable by stomachic digestion. It rebuilds the tissues, and the waste and refuse are excreted by the kidneys and skin as urea and uric acid and its salts.

Hydro-carbons are digested in the mouth and small intestines, are burnt up by union with the respired oxygen, thus supplying heat and force to the body. The waste and refuse are excreted by the lungs and bowels.

About three ounces of nitrogenous and twenty ounces of carbonaceous food are necessary to sustain the life of an adult man in idleness. With these epitomized facts in mind let us consider the importance and use of dietetics in the treatment of disease. The importance has been signalized by Bence Jones, who has said that the effect of diet is far beyond any known remedy. This fact has been so well known for the past century that volume after volume has been written on "dietetics," "diet cures," etc. A few of these have become standard works of authority because of their scientific and exhaustive treatment of the subject, while hundreds of others have had but an ephemeral existence. All have had to reiterate the same facts, because very few new ones have been learned, and, aside from the knowledge of artificially digested food, the student of a hundred years ago knew as well as the student of to-day about what diet was necessary for the sick. True, there was an empirical teaching; they knew nothing of the physiological actions of diastase, pepsin, and pancreatin, but they were all the more practical for that. Our present scientific reasonings on digestion are but the formulation of rules and theories for very old facts. The importance of the subject is made more manifest when we consider how much of the sickness that we are called upon to treat is the result of some error in eating or drinking, and as "removal of the cause" is the first step towards the promotion of recovery, it is easy to perceive how essential it is to know what constitutes proper and improper diet. Life depends upon diet, and the restoration of health depends upon the same principles as its preservation. Disease is the result of the violation of the laws of health, hence the first step towards recovery is to reestablish those laws, and as the material for repair and support must come from diet, we, as thorough physicians, should have a complete *practical* knowledge of dietetics and a proper appreciation of their curative value. But almost a decade of experience among physicians compels me to acknowledge that this is not the case, and that the most lamentable deficiency is in the practical application of the subject. Nature's simple and easily understood remedies are either lost sight of or ignored in the blind endeavor to find a medical specific for every human ill, or to establish an ideal notion, theory, or pathy. For the treatment of chronic affections some good points may occasionally be gained by even observing the *modus operandi* of quacks, homœoquacks, and proprietary medicines, for in connection with either a depurative or inoperative preparation such dietetic and hygienic directions are almost invariably *insisted* upon as would in themselves relieve temporarily, and perhaps permanently, some of the most obstinate cases.

The methods of dietetic treatment of diseases are as

various as are the ills that flesh is heir to, but all of them contain some of the following principles as essential features: In acute diseases *rest* is of primary importance; it is the fundamental principle of their medical and surgical treatment, and the same idea must be carried out in dietetics by remembering what part each organ serves in absorption, assimilation, and excretion, and by avoiding such food as would cause the performance of that function. Of course this plan is only to be pursued while the disease is advancing, and as soon as recovery begins there must be a gradual return to a promiscuous diet, very little at first, just enough to slightly exercise the crippled organ, using as great care as we would in instituting passive motion in a limb that has been fractured. Nature enforces this principle by the loss of appetite that marks the onset of nearly all acute diseases. The dietetic rest of an organ does not necessarily imply a depletory diet, for while it is non-active other organs may be made to perform a compensatory amount of work, and thus sustain or even increase the patient's vitality, so great is the versatility of our organic functions. It is upon this idea that we must act when we obey the command of Graves to feed fevers. In chronic diseases—those in which the natural course is direct from bad to worse until death or some interposing process puts an end to them—every organ must be made to do its utmost; the whole system must be awakened to the threatening destruction. Herein lies the broadest field of action for our subject. No time should be lost; food should be administered as frequently as assimilation and proper amount of organic rest will allow; the appetite should be kept active by using liquid, semi-solid, and solid food, prepared in such a variety of ways as to allow no charge of monotony or disgust. Surprise is frequently a useful element. Instead of leaving the patient to vacillate over his or her likes and dislikes, the nurse should be privately instructed how and what to prepare for each time, and how to serve it in the most appetizing manner. A valuable aid, usually lost sight of, is condiment. Think but for a moment how a savory dish will sharpen our appetites while in health, and I am sure you will perceive its stimulating influence upon a debilitated patient, to whom the flat and insipid preparations usually offered are loathsome or even nauseating. This disgust might frequently be avoided, and the amount of prescribed medicine be lessened. Many of the bitter tonics and carminatives of our *materia medica* are the same as are used in cookery, and are none the less efficacious in a palatable dish than in the nauseous pill or draught. Therefore let the delicate aroma of herbs, celery, and bay leaves pervade the soups; use India curry on starchy foods, and when desirable add *capsicum*, *piper nigrum*, etc., to animal broths and substances. In so doing, if necessary, you can satisfy the qualms of your professional dignity by remembering that in catering to the palate you reflexly stimulate the organs of digestion.

Some articles of diet may be administered simply for their curative effect. A five-ounce cup of strong coffee contains about sixty-six grains of extract, or an equivalent of about two grains of caffeine—quite sufficient to relieve a neuralgia, or a headache and sick stomach after a dose of opium. Beef tea, made red-hot with red pepper, is the very best treatment for delirium tremens. A patient to whom I once administered such a dose, made so strong that I would not

have dared to taste it myself, afterwards told me that it was the most refreshing and cooling drink he had ever taken. A London surgeon to the police told me that he had treated a hundred and fifty cases of delirium tremens with this remedy alone, and had not lost one. The use of chloral in these cases is criminal, and many a death certificate of "delirium tremens" ought to be "heart failure from chloral poisoning." Mucilaginous teas and drinks made from gelatine, isinglass, Irish moss, and flaxseed are very soothing to any inflammation within the digestive track. Green vegetables are necessary to cure as well as prevent scurvy.

An old practitioner, who had spent his early professional life in the country, told me that when he first commenced practicing he used all the ordinary remedies in typhoid fever without any satisfactory results, until the introduction of turpentine by the late Prof. George B. Wood. In it he soon discovered a useful ally, not so much in the drug *per se*, but because convenience and time compelled him to use a thick flour gruel as a vehicle, and the patients were nourished sufficiently to live through the attack.

In the science and art of preparing sick diet there is a most lamentable lack of knowledge, especially among physicians. They know the preparations by name, but not by nature, and the only way to learn the latter is to don the apron and take a practical course from a practical and scientific cook. Such a course was inaugurated last winter in this city and in Boston with a very satisfactory result. The prospect for this season in this city is that the course will be very well attended. It is the only way to learn. I could read you receipts by the score, but it would be as useless as reading off that many medical formulæ.

DISCUSSION.

DR. L. TURNBULL, in opening the discussion, said: In reference to these questions, my opinions are rather of the old-fashioned kind, and I believe in courses of instruction on cooking, which will be of much use to physicians. Dr. Benjamin Rush was accustomed in his lectures to remark that "a physician should spend six months in a kitchen before entering upon his practical career." He desired to heighten the importance of a knowledge of the effects of food, and also the correct way of preparing it. All these advantages could be combined with a course on pharmacy. Physicians should learn how to make beef tea, extract, etc., and similar articles. The important preparations of mush, of Indian and oat meal, for instance, are rarely properly made. They should be prepared over night, so as to be thoroughly gelatinized; if made in the morning just before being served they will not be digestible. In cases of very weak stomachs, many articles of diet may be peptonized with great benefit by using a small amount of a mixture of sodium carbonate and pancreatin, these being allowed to act for a short time at a temperature of about 80° F. Fairchild, of New York, prepares powders containing these peptonized materials in convenient amount. Such peptonized foods are like the old-fashioned preparations made with rennet and warm milk, and will be well borne by delicate stomachs. An article that is often wrongly prepared is barley. It may be softened and extracted with water, or it may be torrefied so as to make a sort of malt extract. In the latter form it is very suitable as a substitute for the diastase-like principle of the saliva in cases where

that secretion is deficient. It can easily be given mixed with other food, as in puddings, for instance.

This summer we have been very successful in relieving the irritability of the stomach and bowels of both children and adults, due to temporary indigestion, by substituting first barley-water alone, and after a time a wineglassful of barley-water, with half a tumbler of milk, or its equivalent of condensed milk.

Too little attention is given to character of water. It is sometimes very bad, containing either injurious mineral or vegetable matter. The Boston water supply was much injured lately by certain sponge forms.

Butter is an article of food which is often impure, and besides objectionable substitutes for it are often sold. The mixtures of animal fats known under the names of oleomargarine and butterine should not be used in the preparation of food.

Beef tea contains often but little nourishment, and in debilitated conditions, such as most cases of typhoid fever, beef essence made not from the round of beef, but from the neck, in which blood is found, will be much more nourishing. A valuable form of beef juice can be prepared by cutting up in pieces fresh beef, and placing it under a block of ice until, by the pressure, all the blood has been extracted. With the addition of a little salt it has been found to be retained by the most delicate stomach, and is very useful in cases of great exhaustion.

DR. ALBERT H. SMITH. The older we get the less disposed we are to rely on medicine and the more on diet. The remarks in the paper in reference to the importance of teaching physicians the art of cooking are deserving of full indorsement. On one point, however, I cannot agree with the author of the paper. He seemed to advocate the use of highly stimulating food in acute diseases; in other words, the methods advocated by Dr. Thomas King Chambers in his fascinating work—a work, however, which has done great injury. Dr. Chambers' idea was that all disease was due to depression, and therefore the remedy was to stimulate the system. This is an attractive theory, but is not true. In cases of disease attended with high temperature, we only add fuel to the flame by the use of stimulating food.

Nature has admirable powers of taking care of herself, even under a starvation regimen. The use of a low form of diet, with refrigerants and depressants, may often be of the greatest benefit. I can look back on my early experience, and recall cases in which, after operative measures, patients have been treated on the theory that plenty of pabulum should be furnished in the system, but such patients have perished. A strong patient will in such cases do much better on a low diet. Adhesive inflammation will be secured more satisfactorily on the low diet system.

DR. J. M. BARTON. I had under my charge during three years a patient who sustained life on about a pint of milk a day; never more than a quart a day. He was a physician who had his own views on questions of diet and therapeutics. Dr. A. H. Smith is right in his position as to the importance of low diet after operations, but in typhoid fever we have a very different indication. In the first case, that is after operations, food frequently acts as an irritant, but in the low fevers the patient is exhausted and needs support.

DR. FORBES. I am reminded of a compliment which I heard the younger Larrey pay to Orfila, the great French chemist. He said that he (Orfila) was the

greatest cook that ever lived. He said Orfila understood the disintegrating power of hot water. The effect of thorough boiling is most important, and since the days of Washington it has been an article of war that beans should be boiled for six hours. In the Crimea marked difference was seen between the French and English troops on account of the superior attainments of the French officers and surgeons in reference to many of the details of a soldier's life, and especially in cooking.

DR. SELTZER, in closing the discussion, said: I did not wish to include in the paper a discussion of the methods of preparing food, but merely to express the idea that it is important that doctors should know what to cook and how to cook. Many articles of food, that as ordinarily prepared are unfit for the sick, can be cooked so as to be palatable and digestible. Mrs. Rorer's method of cooking liver is an instance of this. She exhausts it with water to remove blood, then places it on ice until required, when it is cut into thin slices and toasted; sweetbreads are somewhat similarly prepared.

As to the use of stimulating food, we must judge Dr. Chambers' views by his own method. He draws the line between acute and chronic diseases, not making time the basis of the classification, but the tendency of the disease. Acute diseases tend to recovery, and these he leaves undisturbed; chronic diseases tend to fatal results, and in these he uses a highly nutritious diet, stimulating when a depressed state exists.

In reference to the suggestions made by different speakers as to the importance of systematic instruction of physicians in the art of cookery, I may say that such courses are now being organized. I do not think that such instruction can be advantageously given with pharmaceutical teaching. A woman's taste and tact are essential to the art.

Reports of Societies.

THE AMERICAN GYNECOLOGICAL SOCIETY.¹

THIRD DAY. MORNING SESSION.

A BUSINESS meeting was held at 8.30. DR. A. H. SMITH, Vice-President, in the chair.

The general session was opened at noon. The first paper read was one entitled

MENSTRUATION AFTER EXTIRPATION OF THE OVARIES,

by DR. HENRY F. CAMPBELL, of Augusta, Georgia. The influence of the ovaries in normal menstruation was not questioned, but the object of the communication was to suggest a possible explanation of those cases in which menstruation has persisted after their removal. Where a menstrual discharge has recurred regularly after the performance of double ovariectomy various explanations have been offered to account for this occurrence; it has been attributed to the habit of periodical plethora, to disease of the uterus, and recently it has been held to be due to the incomplete removal of the Fallopian tubes, which are claimed to be the real inciter of the menstrual nisis by Lawson Tait. Without denying or accepting any of these as

the sufficient explanation, the lecturer offered another which had not been hitherto noticed, or received proper attention. Taking into consideration the importance of the ovaries in normal menstruation, it might be anticipated that their removal would affect this function, and that it would be likely to cease, as it usually does. But it is known that conditions of the mammary gland exercise an influence over menstruation, and mental emotions also can affect it. If these remote causes may bring on or check menstruation in a healthy subject with active ovaries, it proves that there exists somewhere in the body behind the ovaries, inciter points to menstruation, a centre presiding over this function in the cerebro-spinal system, which may continue to produce periodical congestion of the uterine mucous membrane, and a sanguineous discharge after the ovaries themselves have been removed. If such inciter points exist it is possible that, for some reason, they may continue to act upon the uterus after ovulation has ceased.

The following case was cited: A young girl, some eight or ten years of age, was brought to him by her parents. They seemed very much alarmed by the fact that the child had menstruated twice, and sought an explanation. The patient was apparently a healthy child, had a good appetite except during her monthly periods, and at the time she came she had her third menstrual flow. It was a source of uneasiness and mortification to the parents, who feared precocious development. Upon investigating the case, however, there was nothing in her conduct or in her appearance to indicate premature development, but there was some enlargement and tenderness of the breasts; the pudendum was not examined. Inquiring carefully if there had been any recent illness, the parents said that she had never been sick but always healthy, and had never had anything but mumps in her life; closer questioning revealed that she had had an attack of mumps within three or four weeks. Having recently attended a case of mumps in a young man with metastasis to the testicle, he concluded that this was an analogous case, the metastatic irritation of the ovaries having excited them to premature activity and the phenomena of the menstrual nisis. He ascertained that the periods were irregular, the last interval being only twenty-one days, and that they were less marked than at first. He told the parents his view of the case, and almost promised them that it would be only a temporary condition. The results were as predicted, all the appearances of the menstrual nisis gradually subsided in the course of a few months, and finally disappeared, leaving the child as before; she returned to her normal condition. Some years later the menses appeared at the proper time, at about fifteen years of age, and the child changed and developed into a young woman.

This case might be cited as one proving that the ovaries are the cause of the menstrual nisis, and this he would not deny; but it also proves that an influence existing outside of these organs may excite their functional activity, as well as that of the uterus, so as to determine the appearance of menstruation.

In another child seen in 1867, the child had more decided evidences of puberty; there was enlargement of the breasts, development of the nipple, enlarging of pudendum; everything indicated a premature condition of puberty, and there had been three or four monthly flows. There was only one way in which this could be accounted for, and this was the existence of an acute

¹ Concluded from page 305

mammary abscess, which had been caused, according to the parents' statements, by the bites of the common "red bug," and subsequent scratching and rubbing to relieve the irritation. However this may be, she had the appearances of menstruation for several periods, after which the generative organs subsided to their normal state of development, and menstruation ceased with the healing of the abscess. This also shows that irritation at another point than the ovaries may cause menstruation; that the ovaries themselves are only one link in the chain of causation of menstruation.

Another case may be referred to in this connection. Dr. Clarke had reported it to the lecturer substantially as follows: Of two sisters in different stations of life, the poor one had a large family, the other had no children, although she was fond of them, and stayed with her sister after her confinements. She was irregular in menstruation, and suffered from amenorrhœa for a very long time. While staying with her sister she put the baby to her breast to quiet it, and in the course of a few days of this practice she found her menses returning, and on her return home she became pregnant, and was subsequently delivered of a living child. This is the statement of a gentleman of refinement and intelligence. There are cases on record in which milk has been made to flow from the breast by suckling a baby even after the menopause; he referred to a case of the kind in a grandmother who had to nurse her daughter's child.

Now do we not see in these various phenomena that there is some other influence at work, — perhaps partially, we do not say wholly, — something which is to be considered in menstruation besides the ovaries and Fallopian tubes? If menstruation can occur in a child with undeveloped ovaries, or in a woman with amenorrhœa, by remote irritation acting through some nerve centre in the spinal cord, it is possible that the same mechanism may act when the ovaries have been removed. Now the hypogastric plexus of nerves must have its innervation from some point in the spinal cord, and experience and observation point to the lumbar enlargement, or the crural bulb, as the precise place. This important nerve centre not only presides over the uterine functions, but receives and transmits impulses from the lower extremities. This portion of the spinal cord continues its activity after having its nervous connection separated. For instance, after amputation of the leg pains are often complained of in the foot or toes. A case was mentioned where repeated operations were performed to relieve a pain not located in the stump but referred to the big toe. The centre in the spinal cord had been long accustomed to receiving impressions from the part, and still continued to refer the irritation to that part, although the part had been removed and no longer remained in connection with the centre. This illustration is given merely to excite thought; the pains are not referred there simply as a habit, but because this is a special centre in the spinal cord which presides over the lower extremities, and may continue active after the leg has been amputated. May it not be true that there exists in the nervous system a special centre which presides over the function of menstruation, and which may continue its activity for a while after the ovaries are removed, just as in the case of the amputated legs or arms?

An objection to this may be raised, that castration nullifies sensuality. So it does when performed in a child, because it prevents the development of the sex-

ual system. It does not do so entirely in the adult. Ovariectomy is not performed in the undeveloped period. The organs and the nerve centres are fully developed, and have been functionally active for years; the lumbar centre has been responding to the irritation not merely of healthy ovaries, but to those organs in a diseased condition, and has thus, perhaps, become unduly sensitive. The fact to be accounted for is that for some reason or other menstruation occurs in certain cases after both ovaries have been removed. Admitting that under ordinary circumstances the ovary is the actual inciter to the nervous centre presiding over menstruation, this explanation of these cases of persistence of menstruation after double ovariectomy is submitted, that the nervous centre continues its activity, and continues to produce the periodical congestion and menstrual discharge from the uterus.

DR. GOODELL said that he was not prepared to admit that menstruation occurred frequently after double ovariectomy, nor to deny that this explanation might be possible where it does occur. As a rule double ovariectomy brings on the menopause. He had noticed that after the removal of both ovaries there is a pseudo-menstruation on the fourth or fifth day, which he always instructed the nurse to expect; it is probably due to the irritation of the ligature. As far as he could recall he had had only two cases in which menstruation had regularly appeared after double oophorectomy. In one there was also a fibroid tumor of the uterus. The patient, a young girl, had lost a great deal of blood, and was in a very prostrated condition. In the course of four or five months she had improved very much, and was able to go out of the house. Menstruation now returned. She applied for operation for the removal of the uterine tumor, but in attempting to enucleate it the structure lacerated, and it was found that it was a sarcoma. The operation was not completed. In another case both ovaries were removed, but menstruation had recurred regularly ever since. The only explanation that had occurred to him was that some of the ovarian stroma had been allowed to remain after operation, as suggested by Kœberle.

This incident recalled the reason why he had given up the vaginal for the abdominal operation in performing oophorectomy. Having in one case removed one ovary successfully, he was removing the other when it tore loose from the grasp of the volsella forceps, and part of it escaped into the abdomen so that he was unable to find it. Menstruation continued, and he afterwards performed the abdominal operation, and found that a small piece of the ovary, not larger than a bean, had been left, but it was sufficient to keep up menstruation. The case terminated fatally. In some cases of oophorectomy, owing to adhesions, it is difficult to place the ligature sufficiently low down to fully clear the ovarian structure. He believed that this fact might account for occurrence of menstruation in some cases.

In conclusion he suggested that the paper would have been more valuable if there had been some statistics of the frequency of the occurrence of menstruation after removal of the ovaries.

DR. EMMET mentioned a case of double ovariectomy in which he had also removed both Fallopian tubes, but menstruation returned, and the patient had menstruated regularly for the last thirteen months, the only difference noticed since the operation being that the periods did not last quite so long as before.

DR. GARRIGUES suggested the existence of a third ovary to account for the discharge, and mentioned a case of a young girl upon whom the operation was performed, and both ovaries were extirpated. She subsequently married, and had a living child. This could only be accounted for on the supposition that there was a third ovary.

DR. THOMAS said that no absolute conclusion had been reached by scientific men as to the cause of menstruation, or the influence of the ovaries upon it. The main point of Dr. Campbell's argument is that there is in some portion of the spinal cord, he thinks in the lumbar region, a centre which presides over this function. The speaker had no experience to report as to this supposition, which rests upon the opinion of the reader. With regard to the results of operation he could speak. He believed that he had removed both ovaries in about fifty or sixty cases. He had followed up these cases as well as he was able, and the impression upon his mind was this,—that where the ovaries are present menstruation is the rule, where the ovaries have been removed menstruation is the exception. It may persist for a time from habit. It is well known that some organs may retain their function after separation from the central nervous system. The heart of a sturgeon will beat for hours after removal from its body, owing to what has been called by Professor Draper "the registering action." In a similar way, in those cases in which menstruation continues after removal of the ovaries, he believes that it is because the uterus keeps up the habit of menstruation, and metrostaxis may occur, as in the case cited by Dr. Emmet. It is not regular as to quantity or time, but is a spurious menstruation. Most of these cases have followed Battey's operation, where the symptoms of menstruation may recur regularly for a year or two, and then the periods become irregular. He had also performed Tait's operation, but had found no difference between them in this respect. Battey's operation, consisting chiefly in the removal of the ovaries, Tait's consisting chiefly in the removal of the Fallopian tubes, and, secondarily, the ovaries, of the two the latter would be less likely to be followed by metrostaxis, because it makes a cleaner sweep. In some European journals cases have been reported in which pregnancy occurred after removal of both ovaries. This, of course, can only be explained by the presence of a third ovary.

About six months ago he had removed an ovarian tumor weighing forty pounds, and finding the other one diseased he proceeded to remove it. One of the assistants asserted that the second was parovarian, but on examination it was distinctly ovarian. Asking for the reason for his belief, the assistant pointed to a third and apparently healthy ovary lying behind the other. As it was normal he did not remove it. He could see no reason, if the Fallopian tube remained open, why such a case should not menstruate and have children. Increasing experience led him to believe that the old view is the correct one, that the ovaries are really the most important organs in menstruation. Of course the associated pelvic organs participate, but he does not believe that the Fallopian tubes have anything to do with inciting to menstruation. His rule is to remove the ovaries, but not the Fallopian tubes unless they are diseased, that is, he performed Battey's operation instead of Tait's, except where the tubes themselves are diseased.

DR. BYFORD said that in discussing this question very much depends upon what is regarded as menstruation. If ovulation is essential to menstruation, then true menstruation does not occur after the ovaries have been removed. Some ovarian stroma must be present before there can be menstruation, but if a mere bloody discharge is called menstruation, then it may frequently occur, but he would call this simply a form of metrorrhagia. He had not had much personal experience with this accident. He had performed double ovariectomy about seventeen times, and, with the exception of the metrostaxis coming on in three or four days after removal of the ovaries, he had not seen a single instance in which the bleeding recurred at regular monthly intervals. Where bleeding occurred it was from other circumstances, and there were no attendant symptoms such as accompany menstruation. Where these constitutional symptoms do recur regularly after the operation he believed that some of the ovarian stroma must have been left. It is sometimes very difficult to remove the ovary without tearing it when there are adhesions. He agreed with the last speaker that the old doctrine of menstruation had not yet been disproved, and the exceptions referred to will not invalidate the rule.

DR. MANN said that of the explanations offered, that there was some ovarian stroma, or there was some disease of the uterus, his experience was in favor of the latter. He had removed both ovaries in five cases, and had not seen regular menstrual discharge afterwards. In one from whom he removed the ovaries and fundus of the uterus, leaving only the cervix, the patient recovered, but subsequently returned because she had a flow. Upon examination malignant disease of the cervix was discovered. It is possible that some other cases of reported menstruation after removal of the ovaries may have a similar explanation.

DR. CAMPBELL, in reply, said that he had not presented statistics because he had not tried to prove the occurrence of menstruation after removal of the ovaries; this every one acknowledged. He had merely sought to give a rational explanation of this fact. He had not sought to determine whether ovulation occurred or not, as there were difficulties about deciding this question by microscopical examinations. In one case, where he witnessed the removal of the ovaries by Dr. Battey, he was positive that not a particle of the ovarian structure was allowed to remain, and yet menstruation persisted. With regard to the existence of a third ovary he was rather skeptical. He had examined bodies for forty years, and had never met with a case in which there was a third ovary, but he would admit that it might be the case, just as there may be supernumerary spleens or kidneys. It might be so in very rare instances.

The object of his communication was to account for the appearance of non-ovarian menstruation after the ovaries have been removed, and upon physiological principles. The separation of an organ from its nerve centre as a rule suspends its functions, and it may be that Lawson Tait's operation may be less likely to be followed by menstruation than ovariectomy because of the more complete separation of the nervous connection between the uterus and the spinal centre governing menstruation. It is not denied that the ovaries are the common inciters to menstruation, and ordinarily these organs act upon the lumbar centre so as to

excite its peculiar action, but exceptionally the irritation may reach this centre from a source independent of the ovaries. Ovulation causes menstruation, and the ovaries are commonly said to be the cause of menstruation. The truth of this proposition was not denied; he had simply endeavored to search a little deeper in order to find something behind the ovaries, a more recondite cause for menstruation, one that would explain its occurrence after the ovaries had been removed, or where they were not functionally active. Habit is no explanation, unless it means nervous influence. The beating of a sturgeon's heart is explained not by habit but by its ganglia contained in its wall. Where some ovarian stroma remains, it is a sufficient cause for the menstrual nixus; but eliminating these cases, there still remain some in which this can only be accounted for by nervous influence. The very fact that menstruation is periodical shows that it is governed by a cerebro-spinal centre. All functions under the control of the central nervous system are intermittent; waking is followed by sleeping, a period of activity by one of rest. The heart, the digestive organs, all follow the same rule. The periodical congestion of the uterus and Fallopian tubes is similarly controlled by the nerve centre, which may continue its activity after the ovaries have been removed.

AFTERNOON SESSION.

DR. WILLIAM H. BYFORD read a paper entitled

REMARKS ON CHRONIC ABSCESS OF THE PELVIS,

in which he reported several cases, including one from the practice of Dr. Bixby. He attributed the cause of these collections generally to a pelvic hæmatocele, or to injury to the perimetrial connective tissue during delivery. In the course of time an extravasated clot of blood becomes softened by serous effusion, and the accumulation of white blood cells gradually becomes purulent, but may subsequently become largely absorbed. The contents may be ichorous, serous, or have the characteristics of ordinary pus. They are always inclosed by a cyst wall, lined with a pyogenic membrane, from which depend a number of teat-like processes or tags. These changes in the cyst are important from the point of view of the treatment. If the collection is a recent one these tags do not exist, and simple puncture or aspiration is sufficient to effect a cure. Where the collection points towards the rectum or bladder there is a tendency for these collections to fill again and again, and sometimes even a free opening into the vagina will not prevent their discharging into the bowel or bladder. When the pus has already made its way into these organs, but is imperfectly discharged, three different modes of treatment may be pursued in different cases: A probe may be introduced into the opening and pushed towards the vagina; when it projects so that it can be felt a counter-opening is made, and this should be made sufficiently large to admit two or three fingers. The object is to enable the operator to introduce his fingers so as to thoroughly explore the cavity, in order to remove all the tags and projections of the lining membrane; a free exit will be given to the discharge, and this will usually be sufficient; if not, a few injections of hot water will usually effect a cure. The second method is to introduce the aspirating needle in the vagina, and having drawn away the collection enlarge the opening to admit the fingers, as before. The third method is to find the

opening in the bladder or rectum and enlarge it, so as to make a free discharge through this outlet, and wash out the cavity daily with antiseptic solutions. The projections should be scraped with a dull curette or spoon, for if they are allowed to remain they are slowly separated and give a gangrenous odor to the discharges, and their removal will obviate their offensive character. There is no danger whatever in using a dull instrument for this purpose, guided by the finger. He gave the notes of a case of pelvic peritonitis and cellulitis, followed by abscess, in a woman who was supposed to have cancer from the fetid character of the discharges. A large abscess was discovered, evacuated, and daily washed with iodine solutions, and although she had been very much reduced she ultimately recovered.

In the early stages, before the cyst walls have undergone these fibroid changes, it is only necessary to evacuate the cyst by simple puncture; but when the lining membrane has undergone this change, simple evacuation is not enough, the walls must be scraped.

He summarized his communication as follows: He looked upon the inner surface of an abscess as similar in structure to an ulcer on the surface of the body, being covered with granulations which produce pus, as in external ulcers. These granulations are sometimes exuberant, sometimes flabby, sometimes large and fungated; they may give rise to healthy pus or unhealthy; in the course of time they may undergo changes and become converted into cicatricial tissue. Serum may be effused into the cyst by endosmosis, the cells become disintegrated, until the whole contents become serous, and may thus become absorbed, leaving a solid tumor of a cicatricial character, as was found in the case of Dr. Bixby, first mentioned.

Dr. THOMAS thought that the reader had done considerable service in following out very closely the changes in the lining membrane of these chronic abscesses. There is a difference in practice with regard to seeking an outlet for these collections with the trocar or aspirator. In his opinion, no more dangerous practice existed in gynecology than that of seeking for these abscesses when they are located high up. If by conjoined manipulation an abscess is positively detected in the areolar connective tissue, then, and only then, may these explorations be made. He had used the aspirator, but only as a means of confirming his diagnosis, not as a method of treatment. The opening should be free. He was in the habit of introducing an exploring needle, and then running a narrow-bladed bistoury along its groove into the abscess. He had found a difficulty in keeping these wounds open, some requiring four or five operations, and had constructed a small glass tube with a flange to keep it from slipping in; a stitch or two through the flange and edges of the opening will keep it in place. By its aid he could have daily injections used, and was in the habit of applying a tampon of tow sprinkled with iodoform. There is one class of cases in which the whole floor of the pelvis becomes involved in a multilocular abscess; the tissues are hard, and the uterus immovable; the patient becomes much emaciated, and looks as if in the last stage of consumption. She is likely to become a confirmed opium-eater to relieve her suffering. It will be found usually that she has been confined to bed for five or six months, and is rapidly approaching her end. Upon examination the uterus is immovable, there is great resistance, and the whole roof of the pelvis seems

like a deal board. In such cases he had adopted the method of Dr. Tait in making an incision along the upper border of Poupart's ligament down to the pus, and evacuated it, using frequent injections. With regard to the curette, he had had no experience whatever in these cases.

DR. GOODELL thought that the suggestion of the curette was a good one; it was entirely novel. The cases he met with are usually chronic; the great majority are not seen *ab initio*, but first come under observation with fistulous openings on the abdomen, nates, or thighs. In a case where the opening is in front above Poupart's ligament, he recommended passing a uterine sound into it in order to make it project into the vagina, so as to make a counter-opening, he then would pass in a drainage tube, and inject frequently.

He uses permanganate of potash in preference to carbolic acid; he reported a case in which a five per cent. solution of carbolic acid had caused convulsions and black urine, showing the absorbing power of the walls of the abscess. In cases that are seen without openings, a different course may be pursued. He had once or twice used the aspirator, and did not think it so dangerous as had been stated; he thought it very valuable when the pus is high up. He had also performed Tait's operation, opening the abscess from above and introducing a tube. He had a case at present of this character, with great emaciation and prostration, and was in doubt about operating. He asked Dr. Thomas's opinion as to the propriety of operating.

DR. THOMAS said that he looked upon the operation as a desperate one, but the condition of the patient is even more desperate. He would not resort to abdominal section in the case mentioned unless it offered the only chance of recovery.

DR. SUTTON said that scraping of abscess walls is the practice in Esmarch's clinic at Kiel, followed by irrigation.

DR. CAMPBELL was not familiar with curetting abscesses, and had merely sought to keep them clean with the syringe and hot water. He afterwards distended the cavity with soft linen, in order to stimulate the walls to repair. He did not regard scraping off granulations as desirable in open ulcers; he regarded them as the natural means of filling up the cavity. He regarded constitutional treatment of the first importance, especially giving iron, and especially recommended the tartarized iron, or the double tartrate of iron and potassium; in these cases of chronic suppuration it favors the formation of healthy granulations. Ricord believed that the recommendation to use this salt in phagedæna was equally valuable as the introduction of the iodide of potassium for secondary and tertiary syphilis. He, in conclusion, referred to a case of a large pelvic abscess from which gallons of pus escaped, which had opened on the thigh. Under daily injections of very dilute Labarraques solution and the internal use of iron the patient greatly improved. He was not disposed to favor the treatment of abscess by the curette.

DR. BYFORD said that he had not attempted anything like a complete treatise upon pelvic abscess, but simply called attention to some forms of it and their treatment. The danger of exciting inflammation by the curette applies only to recent or acute abscess. He had read a paper upon this subject before the American Medical Association at Cleveland.

In cases where there were several openings he had

carried out the treatment with the drainage tube with great success. He did not claim originality for the curette; he had used it mainly to remove those tag-like projections mentioned.

DR. GEORGE J. ENGELMANN, of St. Louis, read a paper on

ERGOT, THE USE AND ABUSE OF THIS DANGEROUS DRUG.

Apologizing for calling up such a trite subject for discussion, he said that the poisonous properties of ergot, though well known to this Society, were not generally appreciated by the profession. He believed that its use should be very much restricted, as it is generally used when it is injurious, and where it may be safely used there are much better means at hand with which to control hæmorrhage. It is never necessary, and can never be relied upon with certainty. The only condition in which it may be useful is post-partum hæmorrhage, but here it is too slow in its operation; there are better methods of controlling the hæmorrhage. Ergot should never be given to expel the contents of the uterus; it produces tonic tetanic contraction, and favors hæmorrhage when its action is past. He would like to see ergot restricted to the non-pregnant condition; there are no conditions in which it is necessary. In the first and second stages of labor its use is generally condemned; in the third stage it is apt to act violently, and produce firm contraction with incarceration of the placenta. If given at all it should not be used until the uterus has been emptied, but cannot be recommended unless given with great care. Massage and pressure with the hand over the uterus will be more prompt and reliable. Given during labor it is liable to produce lacerations of the cervix, vagina, or perineum, or hour-glass contraction and death of the child. The injury which the ergot does is not likely to be discovered at the time, but is found out afterwards, and its cause is unsuspected. The drug is in common use by the general profession for all uterine disorders, and it does a great amount of mischief in incompetent or unskillful hands.

DR. JOHNSON did not think it was employed so recklessly as the lecturer had stated. He did not know of any intelligent physician who would give ergot in the first stage of labor. Having read a paper upon this same subject last winter, Dr. Fordyce Barker had called attention to a class of cases where ergot might be useful. In cases where chloroform has been given it may be administered in the third stage of labor to obviate any tendency to relaxation caused by the chloroform.

DR. CAMPBELL said that he never gave ergot until he was sure that the os was fully dilated, and that no obstruction existed. He always carried ergot with him in his obstetric bag.

In 1836 or 1837 Dr. Milton Antony, in a Charleston journal, wrote some stringent articles upon this same subject, giving the action of the drug, and insisting that it should never be given until the os was fully dilated, and usually not before the birth of the child. He regarded it as a remedy of great power, and even as taking the place of the forceps. Now the forceps are used in many cases in which ergot was formerly given. He never gave it to promote expulsion of the head, but to produce contraction of the uterus. He would not give it during post-partum hæmorrhage, but would give it to *prevent* post-partum hæmorrhage.

Dr. A. H. SMITH indorsed the statements of the paper, and condemned the use of ergot as always calculated to do harm, and often does harm. He denied that chloroform, when properly given during the labor, is likely to be followed by relaxation of the uterus. Ether, on the contrary, often is, because much more of it has to be given to produce *anæsthesia*.

Dr. CAMPBELL said that he never had given ether in his life in parturition, but always uses chloroform. He believed, however, that chloroform is followed by relaxation of the uterus.

Dr. ELWOOD WILSON said that he had used chloroform for years, but had been obliged to give it up finally on account of its relaxing effect and frequent post-partum hæmorrhage after its use. He had seen the same result from the long-continued administration of ether.

He was surprised to hear the remark that ergot should be abolished. He would question the practice of any man who approached a case of *placenta prævia* without ergot. He had had thirty-two cases of *placenta prævia* in which he had used it, and had given it to produce the tonic contraction which has been claimed for it. He was also surprised to hear that it is of no use in post-partum hæmorrhage. He regarded it as of immense value in post-partum hæmorrhage. The difficulty generally is that ergot is given too late, and in too large quantities. He asked if, in the experience of those gentlemen who had used it, they had not noticed that after giving ergot the patient had complained of a flush and heat, and at the same time the uterus contracts, and the bleeding stops. He regarded this action of ergot a very important one. He thought that half a teaspoonful of the fluid extract would produce its effect in about ten minutes, and after expelling the placenta the uterus would go into firm contraction. In his opinion it is bad practice to throw carbolized water into a recently delivered uterus. As regards the use of ergot after abortion, he had been in the habit of giving it all his lifetime, and had never experienced any great difficulty in the treatment except in one case, which he tamponed, unfortunately, and the woman died in thirty-six hours, of peritonitis.

Dr. ENGELMANN feared that he had been misunderstood, as he had not read his paper in full. He meant to bring out in the discussion the possible limitations of the scientific use of ergot, and to direct attention to its general abuse. He did not deny that it could be of service in skillful hands, but, being a powerful poison, it should never be administered by unskillful persons. He spoke of its use among the public by nurses, midwives, and others as being exceedingly dangerous, it being popularly regarded as the great remedy for delayed labor, and patients frequently ask for it if the labor is slow. He had seen cases of arm presentation with the uterus in a state of firm, ergotic contraction, where nothing could be done except to mutilate the child. He believed that the only proper sphere for ergot was when the uterus is empty. He condemned its administration for expelling the contents of the uterus.

After the passage of some complimentary resolutions to Dr. Chadwick, the founder of the Society, for his faithful service for seven years as its secretary, and to Dr. Mundé for his service as treasurer, the newly-elected officers were installed, and the Society adjourned.

OFFICERS FOR 1883-84.

Dr. Albert H. Smith, of Philadelphia, President; Dr. James R. Chadwick, of Boston, first Vice-President; Dr. Samuel C. Busey, of Washington, D. C., second Vice-President; Dr. Frank P. Foster, of New York, Secretary; Dr. Matthew D. Mann, of Buffalo, treasurer.

Next place of meeting, Chicago. Time, the third Tuesday in September, 1884.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

CHARLES H. WILLIAMS, M. D., SECRETARY.

JUNE 18, 1883. Dr. W. L. RICHARDSON presided.

RICKETS AND CONGENITAL SYPHILIS.

Dr. POST exhibited a dog which showed characteristic deformities of rickets, and read a short communication on the Supposed Relationship between Rickets and Congenital Syphilis, in brief as follows;—

Several communications have recently been read before the Surgical Society of Paris on the subject. Parrot, in his paper, gave in detail his well-known ideas in brief as follows: Rickets is the final lesion of the syphilitic germ which has already passed through intermediate steps, and this relationship is established by the study of a great number of patients in the various stages of the disease. He dwelt somewhat upon the traces left on the skin and teeth after the active stage of the disease has passed, and then proceeded to the second part of his paper, which dealt with the bony lesions, and to which alone I wish to refer to-night. These osseous lesions he ranges under three principal types, which correspond to three successive stages of the disease and ages of infancy: first, the stage of osteophytes; second, the stage of gelatiniform softening; third, the stage of spongioid tissue.

The first stage shows itself in the fœtus, and for the first two months after birth. It is characterized by the development about the diaphysis of osteophytes with bony fibres perpendicular to the diaphysis, and the bones where it ought to be sought are the tibia on its internal face, and the humerus at its lower end and posterior aspect.

The second stage, that of gelatiniform softening, shows itself during the first year, and is characterized by the appearance in certain parts of the spongy tissue, and even of the shaft, of a soft, watery, transparent tissue, analogous to jelly, which can end in the cranium by the perforation of the tables and diploë, and at the extremity of the long bones ends in a separation of the epiphyses, and consequent loss of power, to which condition Parrot has given the name of syphilitic pseudo-paralysis.

To the third stage appertains the medullization or decalcification of the bone, which is a continuation of the preceding stage, and differs in nothing from rickets. The child does not necessarily go through all these stages of bony disease, but may skip the first two, presenting only the rachitic stage, exactly as certain stages of acquired syphilis may be omitted.

Such is the shortest possible statement of Professor Parrot's views. He has long held the same ideas, and read a paper embodying them at the London Medical

Congress. They are by no means generally accepted. At the meeting of the Surgical Society of Paris at which Professor Parrot read his paper dissent was expressed, and at a subsequent meeting a paper was presented by Dr. Cazin, of the Berck Hospital for Scrofula, giving a detailed examination of forty-nine rachitic children in the hospital in whom it was impossible to find any sign of syphilis.

Although, as I have said, the identity of these two diseases is not accepted, the authority of Professor Parrot is so great that they deserve serious consideration. If the subject was of sufficient importance to occupy the time of the London Medical Congress, and to fill many pages of their Transactions, a few moments devoted to it here may not be ill employed. My object is to show that rickets occurs in the dumb animals, among whom it is well known syphilis does not occur.

The attempts to inoculate syphilis upon the inferior creation have been continued through a long series of years, and their negative result is tabulated in the ordinary text-books on venereal diseases. The subject recently occupied the attention of Neumann, of Vienna, who has performed a number of experiments which confirm the negative results of previous experimenters. These experiments of Professor Neumann have extended over a year, and number fifty-four inoculations upon a great variety of animals, among which were three apes, which, as a near approach to man, ought to be most eligible subjects for inoculation. These inoculations were made directly from human patients, and most of the subjects of the experiments were kept under observation for a long period. Neumann considered himself justified in concluding that syphilis is exclusively a disease of the human organization.

Auspiß, in commenting upon Neumann's paper, considered that the subject must be left undecided. He believed Neumann's mode of inoculation faulty, but his own experiments by the method he preferred had the same negative result.

Professor Müller gave some exceedingly interesting details of the diseases of animals which most resemble syphilis. Dogs have frequently in the mouth, on the prepuce, and penis growths which resemble venereal warts. These are not transferable by experimental inoculation, though apparently transferable naturally. Hares have an affection which resembles syphilis, but which is of a tuberculous nature. Pigeons show infiltrations on the wings, feet, and head, which are apparently syphilitic, but are really tuberculous. Horses have a so-called chancre, the syphilitic nature of which is doubtful, but which is contagious.

Herr Docent Dr. Mracek spoke of the inoculations of Hänsell, who injectioned the anterior chamber of the eye of rabbits, and tumors resembling syphilitic gummata resulted. These he considered proof of inoculation of syphilis.

Kaposi practically summed up the matter by saying that the so-called positive results could not be considered conclusive until it is possible to convince one's self of the undoubted specific character of the results of inoculation. He had found results similar to Hänsell's in the eye when non-syphilitic inoculation material was used.

Professor Stricker added that he had examined one of the eyes inoculated by Hänsell, and found undoubted tuberculosis.

These men, then, who occupy positions of authority on the subject, reaffirm the previous judgment that

the syphilis of man does not exist in animals; or rather, more logically, that the alleged positive proofs are unreliable, and that up to the present time all proof goes to the establishment of the negation. If the existence of rickets in domestic animals is proved, the proof of the non-identity of congenital syphilis and rickets is as strong as the negative proof in regard to the existence of syphilis in animals; and to show the existence of rickets in domestic animals I exhibit a dog with characteristic deformity.

This dog comes of a family that has long been under observation. I have known three generations. Though never winners of prizes, they have been carefully bred, and have been a healthy and active race, and great favorites with their owners for intelligence and hunting qualities. Certainly none of the immediate relatives of this dog have any disease that resembles syphilis in the human subject; of the mother of the specimen in question I can say that with certainty. The litter to which the dog belonged were fed to a large extent on farinaceous food, and kept for several hours each day and slept at night in a dark and damp cellar. They were all attacked when about two months old with diarrhoea, and their legs soon began to grow crooked. One of them took up his position behind the kitchen stove, and resented the slightest handling, even crying, evidently from pain, when brushed accidentally by his mistress' dress.

When I saw them I found, in addition to a marked curvature of the fore legs, an enlargement of the epiphyses at the wrist, and tenderness on pressure over them. The ends of the ribs were also enlarged, showing the rachitic rosary in a manner which in the human subject belongs to rickets, and nothing else.

The dogs were immediately removed to a place where they had at all times access to the open air, and were fed on animal food. The diarrhoea soon vanished, the deformity ceased to increase, and diminished in various degrees in the different individuals, until in some members of the litter all trace of deformity has practically vanished.

Such a deformity as the dog presents might be attributed, perhaps, to some other disease of bone, — in fact, those who believe in the identity of congenital syphilis must believe the disease to be something beside rickets, — but the history is too striking to be lightly passed over. The ordinary causes of, or at least the ordinary circumstances which precede, rickets — improper food and unhealthy dwelling — were present. The earliest symptoms of rickets are diarrhoea, unusual perspiration, especially about the head and neck, and tenderness, often so extreme as to be manifested on the slightest handling. On removal to better circumstances, or with simply a better diet, recovery takes place, the deformity ceases to increase, the size of the epiphyses diminishes, and the deformity already acquired remains stationary, or improves somewhat. With the exception of the perspiration, which could not manifest itself in the dog, the history, taking the whole litter, was most striking in its resemblance to the ordinary course of the disease in the human child; the only difference lies in the fact that the deformity in these puppies took place in the fore legs, while its most common seat in the human race is in the tibiae. Rachitic arms are common enough in children, but they are seldom the earliest seat of the deformity.

The answer to such facts on the part of the believer in the identity of the diseases must be either that

this dog's parents had syphilis, or his disease is not rickets. The first hypothesis is opposed by all the known facts on the subject. If the second answer is made, and it is the answer given to the artificially developed rickets, it seems equally fair to say that the children with similar symptoms and deformities are not the victims of rickets, but of a disease which should receive some other name.

My argument is simply this: A disease occurs in young dogs which presents all the characteristics, general and bony, of rickets in the human subject, and which, so far as can be argued from history and gross appearances, is identical with human rickets. Syphilis does not occur in dogs; therefore rickets cannot be identical with congenital syphilis.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

The first meeting of the Society after the summer recess was held at the College of Physicians and Surgeons, New York, on the evening of September 24th, when a paper on Adenoid Vegetations of the Pharyngeal Vault and their Relation to Middle-Ear Disease was read by Dr. R. E. Swinburne.

NOMINATION OF OFFICERS. "OLD CODE" AND "NEW CODE" TICKETS.

The nominations of officers for the ensuing year, to be voted on at the annual meeting on the fourth Monday in October, were also made, and two opposing tickets, the one "old code" and the other "new code," were put in the field. The "old code" ticket is as follows: President, Dr. T. Gaillard Thomas; Vice-President, Dr. Charles A. Leale; Secretary, Dr. A. E. Judson; Assistant Secretary, Dr. P. Brynberg Porter; Treasurer, Dr. Henry D. Nicoll; Censors, Drs. Charles McBurney, Charles S. Wood, Richard H. Derby, Charles Hitchcock, and T. Herring Burchard. The "new code" ticket is as follows: President, Dr. S. Oakley Vanderpoel; Vice-President, Dr. Andrew H. Smith; Secretary, Dr. Wesley M. Carpenter; Assistant Secretary, Dr. C. H. Avery; Treasurer, Dr. O. B. Douglas; Censors, Drs. Frederic R. Sturgis, David Webster, Daniel Lewis, F. R. S. Drake, and Joseph W. Howe. The latter nominations were offered by Dr. Sturgis, and the former by Dr. Austin Flint, Sr., who, in proposing the ticket, remarked that he did so at the request of a large number of medical men who are in favor of sustaining the Code of Ethics of the American Medical Association. The gentlemen whose names were on it, he said, were uncompromising adherents of that Code, and their election would mean that the County Society did not approve of the action of the State Society. In conclusion, he requested all friends of the old Code to refrain from making any other nominations, so that their strength might be concentrated on the one ticket. The election is looked forward to with great interest, and the vote will no doubt be the largest ever polled in the Society.

— Recently, at Athlone, Ireland, a man was fined ten shillings for allowing a "wake" to be held upon his child, who had died from scarlet fever.

THE TRI-STATE MEDICAL SOCIETY.

This Society held its ninth annual meeting in English's Hall, Indianapolis, on September 18th, 19th, and 20th. The attendance was larger than at any previous meeting, numbering about two hundred and fifty, and the papers presented were of more than usual excellence and interest, so that the Society may be considered to be in a flourishing condition.

CHANGE OF NAME AND TERRITORY.

It was decided, as suggested by the President, Dr. Wm. Porter, of St. Louis, to change the name of the Society and enlarge its territory, which has hitherto been confined to the States of Illinois, Indiana, and Kentucky, and the cities of Cincinnati and St. Louis.

After some discussion the Society was rechristened, and hereafter will be known as the "Medical Society of the Mississippi Valley." The next meeting will be held in Springfield, Ill., in September, 1884, and Dr. B. M. Griffith, of that place, was elected President for the ensuing year.

The programme included over fifty regular papers, and although most of them deserve special mention space forbids, and I shall only speak of those which were of exceptional interest to the Society.

Dr. A. Morgan Vance, of Louisville, in a paper on

THE TREATMENT OF COMPOUND FRACTURES,

said that he was astonished at the diametrically opposing opinions held by different surgical authorities as to what is the best thing to be done in these cases, some advising to treat them all as open wounds, others to close them and endeavor to reduce them to simple fracture. Dr. Vance gave his method, which was to treat them as simple fractures and put them up in fixed splints, as plaster of Paris, and trust to the thermometer to tell when pus had formed, and it became necessary to open the dressing. He used no antiseptic dressing, expecting some hemorrhage to occur when reaction took place, and the blood to seal and protect the wound. He uses oakum or some other absorbent about the wound.

If the temperature rises to 101.5° F. to 102.5° F. without apparent cause an investigation of the wound is demanded. If this rise should occur during the first forty-eight hours, he gives a mercurial and quinia, and leaves the wound alone. If it occur suddenly on the third and up to the sixth day, he removes the dressing, and allows free drainage.

Dr. Wright, of Olney, Ill., advocated nerve stretching in sciatica, giving cases.

Dr. J. E. Link, of Terre Haute, presented a very interesting paper on

THE USE OF THE ROLLER BANDAGE,

advocating its employment to repress abscesses and erysipelas, and as a dressing for stumps after amputation. He uses successive layers of old sheeting wrapped around the limb so as to put the muscles at perfect rest, and leaving the wound open. The author claims for this method absence of all after-pain, freedom from suppuration and pyæmia, and more rapid healing of the wound. Dr. Link claims never to have lost a case of amputation out of two hundred cases. If his method will do what he declares it will it should be carefully and extensively tested.

DR. H. H. MUDD, of St. Louis, read a paper on

STONE IN THE BLADDER,

comparing the operations of lithotomy and lithotripsy, giving the preference, under certain restrictions, to the latter, and citing cases.

DR. DUDLEY S. REYNOLDS, of Louisville, advanced a new method of treating

OPACITIES OF THE CORNEA

by pricking the part with a tattooing needle, when, by the active vascular inflammation set up, he finds that the opacity is diminished in intensity, and in many cases a fair degree of vision has been restored.

In the discussion on this paper Dr. Post, of St. Louis, stated that Dr. Snellen had used the same method in his practice with good results.

CHLOROFORM IN LABOR,

by DR. G. V. WOOLEN, of Indianapolis, created considerable discussion, the author holding that the anæsthetic should be used freely even to profound insensibility. The general opinion seemed to be that this position was untenable, and that the drug should only be used in moderation, as the full anæsthetic effect exposed the patient to added risk of post-partum hæmorrhage, etc.

DR. S. J. JONES, of Chicago, read a paper on the Influence of Errors of Refraction and Defects of Accommodation of the Eye, which was well received, and also by title a Plea for Early and More Thorough Treatment of the Ear, after which the most successful and last meeting of the Tri-State Medical Society adjourned.

Recent Literature.

On the Pathology of Bronchitis, Catarrhal Pneumonia, Tubercle, and Allied Lesions of the Human Lung. By D. J. HAMILTON, M. B., etc., Professor of Pathological Anatomy, University of Aberdeen. London: Macmillan & Co. 1883. 248 pages.

In this series of studies, originally published in the *Practitioner* in 1879 and 1880, the author has given a description of the appearances observed in the diseases mentioned in the title, based chiefly upon their histological character.

The first half of the book, which treats of the relations of acute and chronic inflammations of the air passages, is especially valuable, since it is only by a close study of the early and insignificant alterations that the later and more marked ones can be interpreted. A well-simplified but careful description of the novel structure of the bronchi is taken as a starting point, great stress being laid upon the manner in which the ciliated columnar epithelium is produced from the more flattened, deeper layers, and upon the existence of a structureless basement membrane supporting these and entirely separating them from the surrounding muscular and fibrous coats.

The changes which occur in acute bronchitis are next described. An acute congestion, such as is found after death by opium poisoning, is probably the commencing stage. This is characterized by a slight desquamation of the epithelium, with great oedema of the basement membrane, and an accumulation of round cells in the fibrous layer of the mucosa. As the dis-

ease progresses these processes become more marked. Hæmorrhage into the inner fibrous layer and basement membrane is associated with the extreme congestion, and the capillaries of the nerve ganglia and trunks are distended with blood.

In the formation of the secretion the cellular parts are considered to be chiefly derived from the proliferating epithelial cells, which are cast off in an immature state, any passage of the accumulated leucocytes and endothelial cells from beneath being prevented by the thickened basement membrane. The watery and purely mucous parts of the secretion are supplied by the glands.

Chronic bronchitis presents itself under different aspects, according as it results from (1) an acute bronchitis, (2) valvular lesion of the heart, (3) inhalation of foreign materials, or (4) chronic interstitial nephritis.

In the first case, the cellular infiltration persists, and an atrophy of the muscular coat is caused by the pressure. The basement membrane still remains intact, however, and forms a sharp line between the germinating epithelial layer and the masses of small round cells below. The cartilage also begins to disappear, being encroached upon from without, its own cells shriveling up and taking no part in the process. The walls of the small arteries are thickened, and the capillaries dilated to small sinuses. The mucous glands are partially destroyed.

When it follows disease of the valves of the heart the inner surface of the bronchi is smooth, and is formed by the basement membrane denuded of everything but a few bud-like projections of germinating epithelium. The membrane itself is thickened and oedematous, and oedema of the fibrous layers replaces the small cell infiltration of the first form.

Where the bronchitis has arisen from the presence of particles of stone or coal which have been carried into the lungs with the breath, the author considers that these have not acted as direct irritants to the larger air passages, but have first found their way into the peribronchial tissue through the alveoli and smallest bronchioles, and then exerted their influence; the basement membrane in this case preventing either the ingress or egress of such minute fragments, since the sputa from these cases is white or yellow, while the lung on section presents a coal-black color. The accumulation of pigment in the lymph spaces and about the blood-vessels destroys the nutrition, and thus gives rise to the irritation which produces catarrh.

After nephritis the appearances are similar to those observed in the first case.

As complications of chronic bronchitis are considered interstitial pneumonia, emphysema, collapse of the lung, and bronchiectasis. The production of some of the forms of the last three can certainly be most readily explained by the mechanical effects of mucous plugs and the forced expiration of coughing, combined with the changed structure of the bronchial walls. Whether, however, the formation of connective tissue follows directly from the accumulated cells, as the author assumes, is not quite so clear, especially since he signals with this the co-existence of tubercle, the relation of which to chronic inflammatory processes being still undecided.

The second part of the book is devoted to the catarrhal processes which take place in the alveoli of the lungs. Considerable space is used in showing that

blood pressure suddenly applied can produce croupous pneumonia without the intervention of any "inflammatory action." The illustrations of the catarrhal pneumonias are very good, and the whole subject is well presented, although not differing essentially from that of the classical writers on the subject. In an appendix he is inclined to think that the bacillus of Koch is of the value of a secondary cause.

The book is well worth the perusal of those who are especially interested in the subject, the illustrations being new and valuable.

Medical and Surgical Journal.

THURSDAY, OCTOBER 4, 1883. J

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY, No. 4 PARK STREET, BOSTON, MASS.

THE PHYSIOLOGY OF THERMAL SENSATIONS.

On the ground of investigations in the Harvard physiological laboratory, Drs. Lombard and Walton have advanced a new theory on the physiology of thermal sensations, the main features of which have been published in the *Centralblatt für die Med. Wissenschaften*, 1883, No. 32.

All efforts on the part of physiologists to find special nerve terminations to receive and special nerve fibres to transmit sensations of heat and cold having failed, these authors explain thermal sensation as a variety of pressure sensation, and suppose both varieties of sensation to be received and transmitted by the same nervous apparatus, the brain being credited with the distinguishing power. Their experiments show that while connective tissue and albumen contract under cold, and expand under heat, elastic tissue and the skin as a whole contract under heat like caoutchouc. The nerve terminations, then, are subject to constant changes of pressure resulting from changes of temperature, and being subject to such changes the sensation must be conveyed to the brain. It is probable, therefore, that it is these changes of pressure which we feel, and which we learn to interpret as sensations of heat and cold by associating ideas in the brain.

An interesting feature of the experiments is that the epidermis is found to be influenced hardly at all by heat and cold, and that the underlying skin when subjected to extreme heat (over 63° C.) contracts in a marked degree, and remains contracted after the heat is removed, leaving the epidermis separated in the form of a blister. This leads the authors to explain ordinary blisters, at least in part, in a similar manner.

The similarity of the sensations received from rapid division of the skin with a sharp knife, and stroking

the skin rapidly with a very hot wire, supports this theory, or, if one prefers, is explained by it, as is the similarity of the impression from a light breeze upon the surface of the body and brushing it lightly with cotton wool.

The practical economists may take a hint from this suggestion of cold abstract science, which, if supported, may extend the domain of the correlation of forces. The possibilities of pressure may, in practical American hands, be developed in time to relieve humanity of some of the embarrassments arising from destroyed forests, exhausted coal fields, and increasing cost of fuel.

It is probably not merely a spasmodic reflex action, nor yet a mere impulse to antagonize by action exaggerated cardiac activity, which leads the lover to press the hand of the beloved. If the present theory is verified we shall suspect that a fine intuition had long ago divined the correlation of pressure and warmth, and that as elastic tissue and the skin in general contract under heat like caoutchouc, pressure is quickly converted into warmth.

The theory advanced by our physiologists is ingenious, plausible, and pleasing to contemplate, and we have merely endeavored to adapt it to the tastes of the purely practical among the profession.

THE TYRANNY OF OFFENSIVE TRADES.

THE pollution of the outer air, that most important article of consumption, in and around all our large cities by noisome trades and manufactories is a growing evil, and one not always easy to deal with successfully. The inherent difficulties are increased by the extreme good nature, as a rule, of the American citizen in these matters, and from his inertia or carelessness about protecting himself from such violations of his primitive rights. An extreme theoretical right to think, and speak, and act as he pleases, apparently results in an extreme reluctance to protest against being imposed upon or robbed by others who are practically emphasizing this theoretical right. Even when protests which cannot be neglected are made, and laws are provided, it is not always convenient for those charged with their execution to enforce them against a dispenser of votes as well as of smells. The upright executor of the law, too, is confronted with the distinction between the injury to health and the simple injury to the æsthetic sense, and with the risk of merely driving an offensive trade from a place where it is a nuisance to one where it becomes a still greater one. The offense of many trades can be greatly mitigated by proper precautions, which often, it is true, increase somewhat the cost of the product and diminish correspondingly the profit of the manufacturer, but here the political-economical intelligence of the citizen must counterbalance his inertia in complaining or his approval of commercial activity, and make him bear in mind that if pure air becomes dear in a direct ratio as manure and soap become cheap, these last may after all cost too much.

Nowhere has the public comfort or the public health been more greatly or more persistently outraged by offensive trades than in the city of New York and its neighborhood. Hence we are very glad to see that five of the manufacturing establishments on Newtown Creek, Long Island, which were recently inspected by the officers of the State Board of Health, and were ordered by the Governor to so modify the processes they employed as to cease to be public nuisances or else discontinue their business, having failed to do so within the required time, were on the 24th of September visited by Under Sheriff Warnoch, with a number of deputies, and compelled to close up permanently. The raids on these stench factories will convince their proprietors, and those of similar places, who have been insolently defying Governor Cleveland's orders, that he is really in earnest in the matter, and that they will at last have to pay some respect to the health and comfort of their fellow citizens. It has been well remarked lately in regard to these very factories, that "the patience of the American people has been illustrated in a striking manner by the way in which rich and poor alike on Manhattan Island and in adjacent cities have for years endured the nauseating odors that have tainted the air for miles around the oil refineries, fertilizer factories, and other sources of vile smells that are to be found in the vicinity of Newtown Creek."

The energetic action of the Board of Health and of the Governor of New York, will, we are persuaded, not be without its good influences beyond the borders of that State.

COPPER AS A PROPHYLACTIC AGAINST CHOLERA, TYPHOID FEVER, ETC., ETC.

FIFTY years ago, during the epidemic of cholera of 1832, a Dr. Méray in Paris recommended and used copper largely as a prophylactic against that disease. The suggestion does not seem to have commended itself very strongly at the time, for it was reserved for Monsieur Burf, of metallo-therapeutic fame, to rescue it recently, and, we believe, briefly, from almost complete oblivion. M. Burf informed the French Academy of Medicine, at its meeting of the 14th of August last, that for more than thirty years he has been devoting himself to a constant study of the efficiency of copper against cholera and other diseases, and the Egyptian epidemic this summer unsealed his lips as to the result of these studies. They lead him to formulate the announcement that persons whose occupation, whose contact with or mere neighborhood to cupric industries cause them to be exposed daily to an impregnation with copper, enjoy generally an immunity against cholera proportioned to their impregnation at the time of the epidemic, and that the exceptions—for such M. Burf acknowledges exist—are about as rare as those among persons properly vaccinated who are attacked with small-pox.

M. Burf's researches lead him to recommend during an epidemic of cholera, the wearing of a copper

belt; the combustion in alcohol lamps in houses of the bi-chloride of copper; the daily exhibition of copper by the mouth or rectum in progressive doses; the use of mineral water containing copper salts, and of vegetables treated with sulphate of copper, for such can be found in France.

At a subsequent meeting of the Academy a M. Bailly who practices medicine at Chambly, where extensive copper works are situated, made some statements which by no means stimulate confidence in the value of M. Burf's thirty years of research or the conclusions which he draws from them. M. Bailly, among other things, stated that Chambly in 1832 was ravaged by cholera, there being eighty-seven deaths out of a population of 1,400, and again during the epidemic of 1849, there were forty-seven deaths, whilst at a neighboring village where there was no copper factory there was no cholera. During an epidemic of typhoid fever M. Bailly himself attended fifty-six cases, twenty-six of whom were workers in copper, and of these four died.

M. Burf in response to M. Bailly, thinks his objections of little force, for, he says, that the metal *altenide* employed in the factory at Chambly is white metal containing only a very minute proportion of copper; moreover he says the town itself is traversed by a stream into which all the waste of the factory is discharged, and under the circumstances the presence of typhoid fever and choleraic diarrhoea is not, he thinks, surprising.

The French Academy of Medicine is not without its "silly season."

THE NEW YORK ACADEMY OF MEDICINE AND THE CODE.

WE have received a circular from Dr. Fordyce Barker, which deprecates the introduction of medical politics into the New York Academy of Medicine, and aims at restoring the fraternal harmony of that learned body, so unfortunately interrupted by the wretched Code controversy in which the profession in New York has been snarled up. Our warm sympathies are with Dr. Barker, as his reference to a previous editorial in this JOURNAL shows, and we hope his will not prove a thankless task.

MEDICAL NOTES.

—A newsman on the Long Island Railroad recently hit upon a novel expedient for dispensing with the services of a dentist. Having an aching tooth which he wished to get rid of, he tied one end of a piece of strong twine around it, and secured the other to the rear end of an express train which was about to leave the Hunter's Point depot. When the cars started he ran along the platform for a short distance, and then dropped suddenly on his knees, while the train went on with the gory tooth dangling in its wake.

—"O monstrous! but one half pennyworth of physic to this intolerable deal of sack!" seems to have been the sentiment of the Commissioner of Internal Revenue on receiving the report of the analysis of

Hostetter's bitters, which was that it is made from a strong alcoholic liquor flavored with various essential oils, as oil of anise, coriander, etc., and contains some vegetable bitters, such as gentian, cinchona, etc. It will be seen that the bitters contain at least sixty-five per cent. of proof spirits, which will be equal to about eighty-two per cent. of ordinary whiskey at eighty per cent. proof, obviously much more spirits than is absolutely necessary to hold the other ingredients in solution. His first impression was as follows: "Containing, as it does, no deleterious drugs and only four per cent. of anything like a drug, I should probably be entirely justified in deciding outright that one who sells it for any purpose is a retail liquor dealer within the meaning of clause four of Section 3244, Revised Statutes, etc." But after longer reflection he naively concludes, and so announces his decision, that if the vendor of this compound sells it *as a medicine* and not as a tippie, and if the purchaser also buys it in the same virtuous spirit, it is not a liquor, and no license is required for its sale. But if either party considers it a drink it is no longer a medicine. Who shall say hereafter that there is nothing in a name?

—The British consul at Bordeaux, in his last report, states: "Low-priced genuine Bordeaux wines must be regarded as non-existing. If the well-known Bordeaux wines are advertised for sale at the same prices as used to be charged ten or fifteen years ago, or in times of exceptional abundance, such wines are not the growth of the vineyard under the name of which they are offered for sale. The prices of the commonest class of Médoc wines (*vin ordinaire*) have increased seventy-five to one hundred per cent. during the last decade. To buy pure genuine Médoc, or other well-known wines of this district, a far higher price must be paid for them than has been obtained for some years. The quantity of adulterated and falsified (so called) 'Bordeaux wine' exported at present annually is very considerable."

—It has been discovered that the flesh of the whale is both nutritious and palatable. Large quantities of it are eaten every fishing season by the men engaged in the capture of the fish, but still larger quantities are wasted. A Norwegian speculator was struck with the fact that some of the immense mass of food thus annually thrown away might be profitably preserved and utilized for consumption on shore. Acting on this idea he arranged with several whaling captains and two meat-preserving firms, and recently he gave a dinner by which, he believes, he has demonstrated that whale flesh may be cooked in various ways, and that it forms a delicious as well as a wholesome article of diet. Some parts of the fish supply materials for an excellent imitation of turtle soup, others resemble beef, and others are almost as white and quite as tender as chicken. The meat can be sold for about half the price of canned beef.

—Prince Bismarck is said to be a particularly intractable and ungrateful patient. He suffers from neuralgia, trifacial and sciatic, and gives his doctor a certain number of days to cure him. If the physician fails he is discharged, sometimes even before the

date allowed; if he succeeds he gets no thanks. The chancellor's wife is a homœopath, and also has much faith in a nerve medicine made of magpies' wings, designed especially as a cure for epilepsy. Such therapeutic measures as these are sandwiched in (and sometimes combined with) the treatment of men like Professor Frerichs. The present attendant is a young man of thirty-three, somewhat notorious for social scandals in Munich.

Correspondence.

THE DIGESTIBILITY OF LOBSTERS.

MR. EDITOR,—The inquiry of your correspondent reminds me that during three years' service at the Taunton Lunatic Hospital I had control of the diet of about four hundred and fifty patients. During the plentiful season all patients not acutely sick had well-boiled plain lobster for supper once a week. Many of the patients were gross feeders, and digestive disorder was by no means unknown among them, but not a single instance of disturbance from eating lobster came to my knowledge.

It is said that "the lobsters of commerce" are boiled for only ten minutes, to prevent loss of weight. The best housekeepers re-cook them, and find that boiling for half an hour renders them far tenderer and more digestible.

To infer that indigestion occurring after partaking of a mayonnaise of lobster, with other rich food, is necessarily due to the lobster is obviously illogical. The "lady," or stomach of the fish, also furnishes an instance of *undistributed middle*, or should do so. And it is unquestionable that safety especially requires it to be fresh, both before and after cooking. Obvious precautions being observed, I believe it to be excellent and wholesome food for all without idiosyncrasy against it.

Yours truly, NORTON FOLSOM, M. D.

THE LAST ENGLISHMAN OF NOTE TO DIE OF AGUE.

MR. EDITOR,—Absence from home prevented me from seeing the Boston Medical and Surgical Journal of July 12, 1883, till this week. In the issue of that date, on page 39, second column, is this statement: "Cromwell was the last Englishman of note to die of ague."

The following extract is from *The Complete Works of Andrew Marvell, M. P.*, by the Rev. Alexander B. Grosart, printed for private circulation, 1875. It may be found in vol. ii., p. 44 to p. 46 of the *Essay on the Life and Writings of Marvell*:—

"54 Harley Street, February, 1874.

"The course of my medical studies led me to consult Morton's *Pyretologia* a few days ago. In that book I found a full account of the sickness and death of Andrew Marvell. . . . Perhaps you may be willing that a physician should translate Morton's medical Latin into modern English. If so, take it as follows: 'In this manner was that most famous man, Andrew Marvell, carried off from amongst the living before his time, to the great loss of the republic, and especially

the republic of letters, through the ignorance of an old, conceited doctor, who was in the habit on all occasions of raving excessively against Peruvian bark as if it were a common plague. Howbeit, without any clear indication, in the interval after a third fit of regular tertian ague, and by way of preparation . . . blood was copiously drawn from the patient, who was advanced in years. . . . He died, who, had a single ounce of Peruvian bark been properly given, might easily have escaped, in twenty-four hours, from the jaws of the grave and the disease.' . . . This seems to me to be a deeply interesting addition to our store of facts respecting a true Englishman.

"SAMUEL GEE, M. D.,
"Fellow of the Royal College of Physicians, London."

The friend of Milton, the author of An Horatian Ode, the "patriot," member of Parliament for Hull, Andrew Marvell, certainly was an "Englishman of note." His death occurred August 18, 1678.

Yours truly, EDWIN FARNHAM, M. D.
CAMBRIDGE, MASS., September 25, 1883.

WAS IT A COINCIDENCE ?

MR. EDITOR, — A., aged nineteen years, while living in New York, was attacked with acute general eczema. He returned to Boston, and slept a few nights with his brother W., and afterwards with another brother, N. In about ten days W. and N. were both seized with this affection, and within a fortnight W.'s lady love also broke out with it. They were all healthy people, and had never before had any skin disease. Only two of the four were surrounded by the same hygienic conditions. Did one catch the disease from the other, or was it a coincidence ?

Duhring says : "Eczema is not contagious. It cannot be acquired from being in contact with or from handling the patient ; nor can it be taken from the discharge."
M. D.

Miscellany.

THE AMERICAN CLIMATOLOGICAL ASSOCIATION.

FORTY members of the profession from different parts of the country responded, either in person or by letter, in acceptance of a call to meet September 25th, in the rooms of the Academy of Medicine, New York, for the purpose of forming a new national society.

It was decided to name the organization "The American Climatological Association," and that the objects thereof should be the study of the Diseases of the Respiratory Organs, together with the influence of climate upon them.

Drs. Tyndale, of New York, Bruen, of Philadelphia, and Garland, of Boston, were appointed a committee to draft a Constitution and By-laws to be submitted to the next meeting, and the same committee was appointed temporarily a Board of Censors.

Drs. Garnett, of Washington, Donaldson, of Baltimore, Bosworth, of New York, Shurley, of Detroit, J. C. Wilson, of Philadelphia, were appointed a Committee of Arrangements for the annual meeting, which will be held in Washington either immediately before

or after the next meeting of the American Medical Association.

The following officers were then elected : President, A. L. Loomis, M. D., New York ; 1st Vice-President, F. I. Knight, M. D., Boston ; 2d Vice-President, W. H. Geddings, M. D., Aitkin, S. C. ; Secretary and Treasurer, J. B. Walker, M. D., Philadelphia.

THE PHILADELPHIA MEDICAL TIMES.

DR. HORATIO C. WOOD has retired from the editorial charge of the Philadelphia *Medical Times*, in which he is succeeded by the assistant editor, Dr. Frank Woodbury. The *Times* enters upon its fourteenth year with the number of October 6th. During the preceding years Dr. Wood has ably identified himself with its interests. Dr. Woodbury is well and favorably known to the readers of the JOURNAL, having represented Philadelphia upon its editorial staff for many years.

SCIENCE AND PSYCHISM.

ABOUT a year ago the Society for Psychical Research was founded in England "for the purpose of making an organized and systematic attempt to investigate that large group of debatable phenomena designated by such terms as mesmeric, psychical, and spiritualistic." This Society is looked upon hopefully as destined to accomplish, by the scientific character of its members and its proceedings, more than any of its predecessors have done in this department where prejudice and ignorance have so long stood in the way of accurate observation of phenomena. It is noticeable that it is the *phenomena* rather than theories explanatory thereof that the Society proposes to investigate. In the *Medical Press* (August 15th) we find a leading article descriptive of what has been already done. The writer, after speaking of the *personnel* of the Society as a goodly number of eminent and well-known men of reputation in the world of arts, letters, and science, says that special committees of its members have for some time been carrying out inquiries in connection with subjects which have elicited considerable discussion both in the press and out of it. Among these "thought reading," or, as it is called in preference, by the Society, "thought transference," has occupied the attention of a committee consisting of Prof. F. W. Barrett, and Messrs. E. Gurney, M. A., and F. W. H. Myers, M. A., formerly Fellows of Trinity College, Cambridge. The results at which they have arrived are communicated in two reports printed in the proceedings of the Society, and the second of which contains some details that are intrinsically interesting on account of the assurance they convey of complete absence of intentional deception. The substance of the reports is thus given in the article to which we refer : —

The subjects of the experiments narrated in these reports were, in one case, the daughters of a clergyman, a member of the Society, and in the other two gentlemen who voluntarily offered themselves to the observation of the committee ; and it may be once for all accepted that no suspicion of collusion, in the objectionable acceptance of the term, is to be entertained in respect to any of the trials.

The experiments conducted with the children referred to were mainly based on the power they respectively possessed to divine the thoughts of others who were concentrating their perceptions on a particular object. One set of results with a pack of playing cards is thus given: "With a full pack of playing cards 248 trials were made with one or more of the committee. Of these twenty-two were guessed completely right on the first trial, and eighteen on the second trial, or a total of forty quite right out of 248, or one right in not quite seven experiments." In addition there were sixty-nine cases in which the card was guessed in part correctly. Omitting the second correct guess, these results show one quite right in eleven experiments; if pure guess-work were the explanation there would have been one right in fifty-two experiments. In the above-mentioned series of trials the sister of the guesser was, as well as the committee, cognizant of the cards selected, but in a second set, during which the committee *alone* knew what had been chosen, sixty-four trials were made with figures ranging between ten and ninety-nine. The result showed one correct guess out of thirteen attempts, whereas pure guess-work simply would give one right in ninety experiments. At a subsequent date, the trials taking place this time in Dublin, Professor Barrett and the subject of the experiment, one of the children, aged fifteen, were seated alone in a room with their backs to each other; the words "hearts," "clubs," "spades," and "diamonds," were written down by Mr. Barrett, and one of these words mentally selected by him; especial care was taken to prevent any kind of movement which might assist the guesser to divine which of the four terms had been hit upon. Out of fifty trials the word selected was rightly named twenty-five times at the first attempt, and a second attempt gave the correct answer in another ten instances. It is noteworthy, too, that during the latter half of the time occupied by the experiment the guessing was slower than at first, and less successful, eighteen out of thirty first guesses being correct in the former, and but seven out of twenty in the latter.

In another series of experiments a "young mesmerist" afforded some very remarkable results, which but for the circumstances under which they were observed might be received with some degree of incredulity. The transference of *pain* impressions was noticed in the following way: A sofa cushion was held by one of the committee before the face of S., the "young mesmerist," who was in addition blindfolded, and thus doubly prevented from seeing the person (B.) whose sensations he was to repeat. Another committee man then pinched or otherwise hurt B., who sat opposite S., holding his out-stretched hand. S. in each case localized the pain in his own person after it had been kept up pretty severely on B. for a time varying from one to two minutes. The results are thus rendered:—

Part of B. made painful:—
Left upper arm.
Lobe of right ear.
Hair on top of head.
Left knee.

Answer of S. (by pointing):—
Left upper arm.
Lobe of right ear.
Hair on top of head.
Left knee.

The committee next drew a series of geometrical diagrams which were then placed in view of B., but in such a way that S. could not possibly perceive them by sight. In each case S. described them correctly, but with the difference that he reversed them

in position, that is, by describing the apex of a triangle, for instance, as below when it was drawn upright, etc. Further, after B. had attentively looked at drawings of the most fanciful description made by the committee, holding the while S.'s hand (the latter being blindfolded), S. reproduced the drawings in such wise that a close resemblance to the original was apparent, allowing for the blinded condition of his eyes, and in no case was there the smallest possibility that S. could have seen the figure, nor did B. touch S. while the figure was being drawn.

LEAD-POISONING FROM CANNED FOOD.

DR. MAGRUDER¹ describes a case of well-marked saturnine paralysis, which he traced to a contamination with lead of the tin lining of some cans containing corn, of which the patient, a lady, had partaken.

The corn was put up by a recipe that required the use of tartaric acid. The contents of several cans was tested, and the presence of lead detected. This must have been derived either from the coating of the cans or the solder, or both.

Upon applying a drop or two of nitric acid to the surface of the can, allowing it to dry, and adding a solution of iodide of potassium, there was found the characteristic yellow spot. The same test was then applied to a number of cans in which food had been preserved, and in all evidence of the presence of lead was found. A more extended chemical analysis of a number of scraps of tin of which cans are made found only two which did not show its presence.

The writer quotes other observers to show that much of the coating upon the cans is not pure tin, but an alloy with lead. We are not as yet in possession of any facts which show tin as forming any compounds with the vegetable acids which give rise to poisonous effects, either acute or chronic, but we do know that lead forms such compounds.

Among other authorities Dr. Thomas Antisell, principal examiner of chemicals in the Patent Office, makes the following statement: "It is well known that all commercial tin is alloyed with lead, even up to the grade known as pure tin-foil, and the manufacture of tinned cans for the canned-food industry must place the food so preserved in the condition most likely to contain lead salts mixed with the organic matter; this is particularly liable with canned fruit."

The writer quotes from *The Quarterly Compend. of Medical Science*, July, 1883, an account of an outbreak of lead poisoning among 150 men of a regiment in the Southern Tyrol, one case ending fatally, and forty-five requiring to be treated in hospital, besides others who were not disabled for duty. The cause of the outbreak was traced to the tin-lined copper vessel in which their food was cooked, the coating of which contained lead. This shows the danger of poisoning from the coating used in tinning. He concludes:—

"When we consider how much canned food is consumed we should expect to find reports of a very large number of cases of poisoning from this source if lead is present in the coating of the cans. But such is not the case. Very few, as far as I have been able to ascertain, have been reported. This may be owing to the fact that only a comparatively small number of

¹ Medical News, September 8, 1883.

physicians report cases. It may also be due to the fact that many minor forms of lead-poisoning have not been recognized and treated as such. Now there is no difficulty in diagnosing a case of well-marked lead-poisoning, but it is not so with slighter cases. Several other members of the family in which my case occurred complained of a bad taste, pains in limbs, general malaise, numbness of the hands and wrists, etc., which would not have been ascribed to that cause had not my attention been called to them in the other case. I found then the characteristic blue line on the gums. The first cases which occurred among the soldiers of Southern Tyrol, reported above, were treated as muscular rheumatism."

SAYRE ON CLUB-FOOT APPARATUS IN CASES OF CONTRACTURE.

DR. LEWIS A. SAYRE, in a clinical lecture reported in the *Medical and Surgical Reporter* (August 18th), speaks as follows regarding the application of corrective shoes in certain cases of talipes:—

"This boy, whom I here present to you suffering from club-foot, came to me from Sing Sing, and thinking the case would be of material interest and practical value to you, I have brought him here to-day to show you an instrument which he has been wearing, and which is called, I believe, the *extension* club-foot shoe, and is perhaps a more recent device for the treatment of this deformity than what I have hitherto brought before you.

"This boy is five years of age, and last fall the parents state that they noticed 'that the left foot was turning over and inwards.' In January, 1883, he was taken to the University College, and from there he was sent to the Dispensary at Fifty-Ninth Street, where they applied this extension club-foot shoe. The parents inform me that this instrument was applied four times daily, being left upon the foot for five minutes at each application. This is the second case that has recently come under my notice in which this instrument has been applied, and I cannot condemn its application too strongly, as being most inhuman in such cases as this.

"But before applying this instrument to the foot let us carefully examine this case before us and ascertain the condition of these tissues, which, at first appearance look to be contracted, but which, as I have previously examined the case, I know to be *contractured*; by this term I mean that these tissues have undergone structural change. To ascertain if this be true we now endeavor to flex the foot upon the leg, and by this means put both plantar fascia and tendo Achillis upon the stretch. You will now observe that, my assistant holding the foot in this position, I make point pressure upon these contractured muscles with my thumb, and instantly there is a spasm passes up the leg, and the boy cries with pain. This reflex spasm, which you here observe we secure in both tendo Achillis and plantar fascia, indicates that both tendon and fascia have undergone structural change, and are then what I call contractured. And no effort to stretch these tissues to their normal length short of rupturing them can afford the slightest possible relief. On the contrary it only causes inflammation in the parts and increases the deformity.

"The mother told me that the extension was made

with these instruments to the greatest point of endurance of the boy from January until the latter part of March, and that during this time the deformity has gradually been growing worse, and the boy has become so irritable and nervous from the torture he has endured from these instruments that she can do nothing with him, and has abandoned all treatment.

"I cannot impress upon you too strongly that when any tendon, muscle, or fascia has undergone this structural shortening, no amount of force short of actual rupture of the tissues can remove the deformity. Why, then, should you subject your patient to this constant agony of useless efforts to secure impossible results by such means as I have just shown you. How far more skillful and creditable, then, is it to the profession to perform the simple operation of tenotomy in such cases as these; you, by this means, at once relieve your patient of his deformity, and the pain, compared to rupture by mechanical force, is insignificant."

ALOPECIA PREMATURA.

THE *Edinburgh Medical Journal* reproduces from the *Berliner klinische Wochenschrift* (No. 16, 1883), the following note: O. Lassar has continued his observations on the nature of premature baldness, and has further convinced himself of the communicability of at least the form associated with daudruff. When the hairs which fall off in such cases are collected, rubbed up with vaseline, and the ointment so made is rubbed among the fur of rabbits or white mice, baldness rapidly makes itself visible on the parts so treated. That this is not due to the vaseline was shown by anointing other animals with the vaseline alone, which produced no effect whatever. He considers that the disease is spread by hairdressers, who employ combs and brushes to their customers, one after another, without any regular cleansing to these articles after each time they are used. During frequent visits to the hairdresser's it can scarcely fail that brushes are used which have been shortly before dressing the hair of one affected with so common a complaint as scaly baldness. Females, he thinks, are less often affected with this form of baldness, because the hairdresser more frequently attends to them at their own homes, and there uses *their* combs and brushes. In order to prevent, as far as possible, the commencement of alopecia prematura, the hair should be cut and dressed at home and with one's own implements, and these thoroughly clean. When it has begun, the following mode of treatment is suggested: The scalp is to be daily well soaped with tar or fluid glycerine potash soap, which is to be rubbed in for fifteen minutes firmly. The head is then to be drenched with, first, warm water, and then gradually colder water. A two per cent. corrosive sublimate lotion is next to be pretty freely applied. The head is then to be dried, and the roots of the hair are to have a one half per cent. solution of naphthol in spirit rubbed into them. Finally, a pomade of one and a half to two per cent. of carbolic or salicylic oil is to be used to the head. This treatment has now in many cases brought the disease not only to a stand, but the hair has been to a considerable extent restored.

— At Baden the use of live pigeons has been forbidden at the shooting matches.

REPORTED MORTALITY FOR THE WEEK ENDING SEPTEMBER 22, 1883.

Cities.	Population by Census of 1880.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from				
				The Principal Infectious Diseases.	Consumption.	Diarrhoeal Diseases.	Typhoid Fever.	Diphtheria and Croup.

Deaths reported 2735 (no report from Buffalo): under five years of age, 1119; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 692, consumption 402, diarrhoeal diseases 282, lung diseases 198, diphtheria and croup 123, typhoid fever 108, malarial fevers 65, scarlet fever 50, whooping-cough 21, cerebro-spinal meningitis 15, small-pox 15, measles 10, puerperal fever eight, erysipelas four, typhus fever one. From *malarial fevers*, St. Louis 21, New Orleans 14, New York 11, Brooklyn six, Philadelphia and Chicago four each, Baltimore three, Providence and New Haven one each. From *scarlet fever*, Chicago 10, New York nine, Philadelphia eight, St. Louis seven, Baltimore five, Boston four, District of Columbia three, Brooklyn two, Fall River and Gloucester one each. From *whooping-cough*, New York seven, District of Columbia four, Brooklyn three, Baltimore and Pittsburg two each, Philadelphia, Chicago, and New Orleans one each. From *cerebro-spinal meningitis*, New York eight, Lowell two, Philadelphia, Chicago, Boston, Baltimore, and Providence one each. From *small-pox*, New Orleans 11, Philadelphia three, St. Louis one. From *measles*, New York three, Philadelphia, Brooklyn, and Chicago two each, Baltimore one. From *puerperal fever*, Brooklyn and St. Louis two each, Chicago, Pittsburg, Milwaukee, and Providence one each. From *erysipelas*, New York three, Brooklyn one. From *typhus fever*, Baltimore one.

In 40 cities and towns of Massachusetts, with an estimated population of 1,159,235 (estimated population of the State 1,922,530), the total death-rate for the week was 17.62 against 22.45 and 21.21 for the previous two weeks.

In the 28 greater towns of England and Wales, with an esti-

mated population of 8,620,975, for the week ending September 8th, the death-rate was 20. Deaths reported 3305: diarrhoeal diseases 463, acute diseases of the respiratory organs (London) 156, scarlet fever 96, fever 76, whooping-cough 51, measles 43, diphtheria 17, small-pox (Birmingham 12, Sunderland three, London and Hull one each) 17. The death-rates ranged from 14 in Oldham to 30.5 in Brighton; London 16.6; Birkenhead 17.6; Bristol 17.9; Nottingham 19.6; Leicester 21; Liverpool 21.9; Sheffield 22.8; Wolverhampton 24.2; Leeds 24.5; Birmingham 26; Manchester 28. In Edinburgh 16.6; Glasgow 23.4; Dublin 24.5.

For the week ending September 1st, in 168 German cities and towns, with an estimated population of 8,645,725, the death-rate was 25.4. Deaths reported 4226; under five years of age, 2336; consumption 514, diarrhoeal diseases 346, lung diseases 273, diphtheria and croup 144, scarlet fever 89, typhoid fever 68, whooping-cough 67, measles and r  theln 42, puerperal fever 22. The death-rates ranged from 13.7 in L  beck to 33.2 in K  nigsberg; Breslau 31.3; Munich 31.4; Dresden 28.3; Berlin 29.9; Leipzig 20.8; Hamburg 24.6; Cologne 21.3; Frankfurt 17.1; Strasburg 25.4.

For the week ending September 8th, in the Swiss towns, there were 34 deaths from diarrhoeal diseases, consumption 16, lung diseases 10, whooping-cough four, diphtheria and croup three, measles one, typhoid fever one. The death-rates were, at Geneva 10.3, Zurich 4, Basle 17.5; Berne 11.3.

The meteorological record for the week ending September 22d, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

Date.	Barom-eter.		Thermom-eter.		Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM SEPTEMBER 21, 1883, TO SEPTEMBER 28, 1883.

VICKERY, RICHARD S., captain and assistant surgeon. Relieved from duty in the Department of the Platte, October 1, 1883, and to report in person to the commanding general, Department of the Columbia, for assignment to duty. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

WEISEL, DANIEL, captain and assistant surgeon. Relieved from duty in the Department of the East, October 1, 1883, and to report in person to the commanding general, Department of the Platte, for assignment to duty. Paragraph 7, S. O. 211, A. G. O., September 14, 1883.

BREWSTER, WILLIAM B., first lieutenant and assistant surgeon. Granted leave of absence for two months from October 1, 1883, with permission to apply for an extension of four months. Paragraph 1, S. O. 107, Military Division of the Missouri, September 15, 1883.

STRONG, NORTON, first lieutenant and assistant surgeon. Now on duty in the field near Fort Thornburgh, Utah, to accompany command to Fort Douglas, Utah, and there await further orders. Paragraph 2, S. O. 107, Department of the Platte, September 17, 1883.

APPEL, Aaron H., first lieutenant and assistant surgeon. The leave of absence granted July 20, 1883, extended one month. Paragraph 10, S. O. 211, A. G. O., September 14, 1883.

DE LOFFRE, A. A., captain and assistant surgeon. Assigned to duty at Fort Niagara, N. Y. Paragraph 5, S. O. 182, Department of the East, September 27, 1883.

HAVARD, VALERY, captain and assistant surgeon. Assigned to temporary duty at post of San Antonio, Texas. Paragraph 10, S. O. 120, Department of Texas, September 21, 1883.

REED, WALTER, captain and assistant surgeon. Relieved from duty at Fort Omaha, Neb., and assigned to duty as post surgeon, Fort Sidney, Neb. Paragraph 5, S. O. 103, Department of the Platte, September 22, 1883.

SHANNON, W. C., captain and assistant surgeon. Assigned to duty at Fort Bridger, Wyoming. Paragraph 3, S. O. 102, Department of the Platte, September 19, 1883.

APPEL, A. H., first lieutenant and assistant surgeon. Assigned to temporary duty at Fort Warren, Mass. Paragraph 3, S. O. 181, Department of the East, September 25, 1883.

CARTER, W. F., first lieutenant and assistant surgeon. Assigned to temporary duty at Washington Barracks, D. C. Paragraph 5, S. O. 182, Department of the East, September 27, 1883.

RICHARD, CHARLES, first lieutenant and assistant surgeon. Relieved from further duty at Creedmoor, New York, to return to his proper station, Fort Adams, R. I. Paragraph 1, S. O. 180, Department of the East, September 24, 1883.

AMERICAN ACADEMY OF MEDICINE. — The American Academy of Medicine will meet at the New York Academy of Medicine on Tuesday, October 9th (three o'clock), and Wednesday, October 10th. The address, by Dr. H. O. Marcy, of Boston, Mass., President, will be delivered on Tuesday evening, October 9th, at eight o'clock, on The Recent Advances of Sanitary Sci-

ence; the Relations of Micro-Organisms to Disease (illustrated by micro-photographs projected upon the screen).

The following papers have been promised for the general meetings: —

Dr. L. S. Pileher, of Brooklyn, N. Y., on The Relations of Medical Journalism to Higher Medical Education in America.

Dr. Traill Green, of Easton, Penn., on The Imperfection of Technical Studies as a Means of Mental Culture.

Dr. Benjamin Lee, of Philadelphia, on The Value of an Acquaintance with Botany as a Preliminary to the Study of Medicine.

Dr. Charles McIntire, of Easton, Penn., Is it Fair? The Study of the Comparative Political Position of the Medical Profession in the United States.

Dr. A. D. Rockwell, of New York, on The Exact Value of the Electrolytic Method.

Dr. J. Cheston Morris, of Philadelphia, The Milk Supply in Large Cities.

Dr. Charles E. Cadwalader, of Philadelphia, Considerations upon the Public Provisions for the Care of the Indigent Insane.

Dr. A. D. Rockwell, of New York, The late Dr. George M. Beard, a Sketch.

Report of the Committee on Laws of Medical Practice in the United States and Canada (Drs. Dunglison and Marcy).

RICHARD J. DUNGLISON, M. D., Secretary.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The meetings of the Section for Gynecology and Obstetrics will be held on the third Wednesday of each month. Members desiring to present communications are requested to send the titles of their papers to the Secretary as early a date as possible. The first meeting will be held on October 17th at 19 Boylston Place, at eight P. M. Dr. C. P. Strong will report an Unusual Case of Obstetrics.

J. B. SWIFT, Secretary, 78 Charles Street.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Clinical Medicine, Pathology, and Hygiene will meet at 19 Boylston Place, on Wednesday, October 10th, at 7.45 o'clock. The following papers will be presented: Dr. G. L. Walton, The Neglect of Ear Symptoms in the Diagnosis of Diseases of the Nervous System. Dr. A. F. Holt, Medical Examiner for Middlesex, Sudden Death from Hæmorrhage from the Hepatic Vein. Dr. George B. Shattuck, Kairin as an Antipyretic in Typhoid Fever, with cases.

ALBERT N. BLODGETT, Secretary.

GYNÆCOLOGICAL SOCIETY OF BOSTON. — The next regular meeting will be held on the second Thursday of October, at the Medical Library Rooms, at four o'clock P. M. M. D. Church, M. D., will read a paper on Post-Uterine Abscess. Lunch served at close of session.

HENRY M. FIELD, M. D., Secretary.

DEATH. — Dr. James A. Fleming died at the Massachusetts General Hospital, September 30th, at three P. M., of typhoid fever, supposed to have been contracted while in camp with the Ninth Regiment, M. V. M., of which he was surgeon.

Original Articles.

POSSIBLE CEREBRAL ORIGIN OF THE SYMPTOMS USUALLY CLASSED UNDER "RAILWAY SPINE."

BY G. L. WALTON, M. D.

RECENT investigations have shown that the terms "spinal concussion" and "railway spine," long in use to designate a set of symptoms following severe injury, are not only inexact, but misleading, in that they direct attention to the spine as the seat of a disturbance which may be, in part at least, situated in the brain.

In the extensive literature on "railway spine" attention seems for a long time to have been drawn away from the fact that the brain is at least as liable to injury from a jar as the spinal cord, while under the ambiguous name "spinal concussion" have been grouped all the nervous symptoms following accident, even in those cases in which organic lesions have been found in the spine on post-mortem examination. This is evidenced, for example, in the work of Erichsen on this subject.

In 1881 Dr. Hodges¹ made an important step towards the classification of these injuries by insisting on the separation of the organic from the inorganic affections of the spinal cord following accident.

Page² has shown that the former are exceedingly rare as long as the vertebral column remains intact. With regard to inorganic injuries to the cord in an accident he regards the term spinal concussion as one having little or no support in fact, and is inclined to class the symptoms hitherto attributed to spinal concussion under hysteria without committing himself to any exact theory as to the physiological sequence giving rise to the hysterical condition.

Dr. J. J. Putnam,³ after reporting two cases in which typical hysterical symptoms were found following injury, has emphasized the importance of seeking among the seemingly vague set of symptoms those which are typical of hysteria, a disease generally acknowledged to have its seat in the cerebral (certainly not in the spinal) centres.⁴

That the brain should be the chief sufferer from an accident rather than the spinal cord seems reasonable, both in consideration of its physiological and of its anatomical relations.

With regard to the former, the cerebral centres represent a far higher development of function, and to perform this function must have a more delicately organized intimate structure than the lower centres of the cord, which preside over the more simple reflex activities of the body. This fact alone should render them more liable to derangement from a jar as resulting from a fall or collision in which both brain and cord must participate.

With regard to the anatomical relations of the two organs, the spinal cord hangs suspended in a cavity much larger than itself, and is surrounded by an amount of loose areolar adipose tissue and fluid so great in relation to its own weight as to diminish materially the liability to injury from a shock; the brain, likewise enclosed by an unyielding case of bone, and itself much heavier than the cord, lies in compar-

atively intimate connection with its case, the dura mater of the brain forming, in fact, the periosteum of the skull. Certainly the facts bear us out in the supposition that the cerebral centres do suffer, whether directly or reflexly, for although pain in the back, weakness in the extremities, etc., seem generally to draw attention to the spine, these symptoms are rarely unattended by irritability, fretfulness, emotional tendency, and inability to confine the attention. These can only be the result of derangement in the higher cerebral centres. Now if careful search elicits such abnormalities of sensation and motion as can only be attributed to cerebral disturbance, it must be acknowledged that the brain rather than the spinal cord is to be credited with being the chief seat of the difficulty. This conclusion is alone a great step towards clearing up these cases, whether the disturbance of function in the cerebral centres be considered due to simple concussion, vaso-motor irregularity, or to reflex influence from injury to other (for example, abdominal) organs. The physiological arguments on the latter points are still so obscure as to render it hardly advisable to discuss them here.

The practical importance of seeking to classify the nervous symptoms resulting from injury is evident. "Railway spine" has offered and will continue to offer a frequent subject for litigation, and any classification of symptoms which will enable us to bring it, if only in part, under a form of disease already understood, and which will enable us to distinguish the real from the feigned, must be of the greatest practical value.

That such symptoms really do exist is shown, for example, by a case recently reported in its main particulars by Dr. Putnam,⁵ and fully by the writer.⁶ The case was that of a fireman, not a claimant for damages, who, after a severe fall on his side from his engine, suffered, amongst other symptoms, from mental excitability and despondency, with a tendency to weep on slight provocation. Examination revealed left-sided hemiparesis and hemianæsthesia limited sharply by the median line. He also had lost to a certain degree, and in the manner characteristic of hysteria, the senses of sight, hearing, smell, and taste on the left side. The temporary disappearance of the symptoms on the application of the magnet showed that they were of functional, not organic, origin, and their seat (involving the head and special senses) absolutely precluded spinal origin.

In this case at least these symptoms enabled us to classify the nervous injury under the head of hysteria. Not the vague hysteria of former times, but the functional disturbance of the cerebral centres which modern research, as set on foot by Professor Charcot, has shown to follow given laws, and to offer pathognomonic characteristics.

The importance of always searching for hysterical hemianæsthesia in cases of injury is the greater in that just this set of symptoms, besides failing to attract the patient's attention, may, and frequently does, pass under the eyes of careful medical observers unnoticed unless especially sought for.

It may be well at this point to mention briefly the chief symptoms to be looked for in establishing hemianæsthesia in a hysterical patient or in a sufferer from "railway spine."

It is not in place here to mention the numerous pre-

¹ Boston Medical and Surgical Journal, vol. civ., p. 861.

² Injuries of the Spine and Spinal Cord, Herbert W. Page, A. M., M. C. Philadelphia. 1883.

³ Boston Medical and Surgical Journal, September 6, 1883.

⁴ Dr. Putnam informs me that since the publication of his article he has met with a third case suffering from typical hysterical hemianæsthesia after accident (railway).

⁵ Boston Medical and Surgical Journal, September 6, 1883.

⁶ Archives of Medicine, New York, July, 1883.

cautions and counter-tests always necessary in examining into subjective conditions. The left side is by far the oftener attacked. On the side affected loss of sensation appears, varying in degree from inability to feel a light touch to complete loss of feeling, so that a pin can be thrust through a fold of the skin while the patient's eyes are closed without his knowledge. It is, perhaps, not superfluous to remind the observer that the eyes must invariably be closed during the testing, for if the patient sees, he is apt to think he feels, that his skin is touched. This is, perhaps, the principal reason why the anæsthesia generally escapes the patient's notice. If doubt exists as to loss of sensation, comparison with the corresponding point on the other side of the body is an essential aid unless that side happens to be also anæsthetic. The disturbances of special sense (though rarely suspected by the patient on account of their unilateral character), when present, offer marked peculiarities. Substances readily smelled with both nostrils open are unperceived (supposing the anæsthesia to affect the left side) with the right nostril closed. If the tongue be protruded with the eyes shut and the patient told to draw it back when he tastes anything, it remains quiet while quinia, for example, is placed on the affected side, but is drawn back instantly when it is placed on the other.

The sight with the affected eye is feebler than with the right, the field of vision is concentrically retracted, and the patient is unable to distinguish certain colors with the unaffected eye closed. The first to disappear is generally violet, then green and yellow; red and blue usually persisting unless the degree of anæsthesia is excessive.

The hearing (allowance being of course made for disease of the ear itself) is less acute on the affected side, perception for sounds conveyed through the bone and that for high tones being first lost.

Symptoms not to be overlooked are mental irritability and emotional tendency.

In order to absolutely establish the diagnosis a large horse-shoe magnet, or electro-magnet, should be placed near some spot of the anæsthetic side and left quietly there for say an hour. In the majority of cases the anæsthesia will be diminished, and perhaps entirely disappear or pass to some other part of the body, oftenest to the corresponding spot on the other side, which constitutes the so-called transfer.

The fact that many observers claim that the mind and not the magnetism is the potential factor in this phenomenon does not lessen its diagnostic value, as its presence in either case absolutely establishes functional anæsthesia.

With regard to the motor functions in this disease, there exist as a rule a certain degree of paresis affecting all the muscles of the side involved, so that the grasp, for example, as measured by the dynamometer, is decidedly feebler than on the sound side.

The reflexes are generally altered in character, degree, or both, the tendency being towards exaggeration.

The writer has recently had opportunity to examine a patient exhibiting the symptoms of hysterical hemianæsthesia in a characteristic manner, with no plausible explanation of their origin except the explosion of a shell in the patient's vicinity. The case, though not coming under the class ordinarily designated "railway spine," is interesting in connection with the discussion of that subject, as strengthening one link in the chain of evidence, in that it substantiates the fact

that hysterical hemianæsthesia may follow a mechanical shock.

It should also be remarked beforehand that the purely functional symptoms in the case were complicated to a slight degree by the presence of certain organic changes for which no other plausible origin can be found than the concussion produced by the accident. These organic changes are atrophy of the optic nerves (probably secondary to the concussion), rupture of both drumheads and purulent inflammation of both middle ears, and (probable) hæmorrhage into the inner ear on the right, which was the side on which the shell exploded.

The temptation is great to assume an organic origin for the symptoms which have been classed as hysterical, but careful study of their nature renders such an assumption extremely improbable.

The patient, examined in conjunction with Dr. H. W. Bradford and Dr. E. D. Spear, is a man forty-one years of age, an American, formerly a lamplighter. There seems to be nothing in his family history pointing to nervous or mental disease. He was himself well and stout until he entered the army in 1861. Up to this time his sight and hearing were good. In 1862 a shell exploding near him he staggered to a tree unable to see or hear. Sight was recovered, and hearing to a certain degree. From this time on the patient experienced recurring "blurs" before his eyes, with intervals during which he saw very well. From the time of the accident the hearing remained so poor that the patient's neighbor had to pluck his sleeve in order that he might answer to his name at roll call, and he became unfit on this account for single picket duty. The hearing was from the first worse on the right.

In October, 1864, he was shot through the left thigh, the ball doing also some injury to the testicle. Patient remained about three months in the hospital, during which time he remembers numerous attacks of blindness similar to those experienced after the bursting of the shell. When he began to walk about in the hospital he was troubled by pains in the back, running down the leg, and in the testicles. On attempting to walk at that time he found that motion was greatly impaired in the left leg, which was atrophied, felt numb, and was drawn up so that the heel could not be put to the floor. The leg shook violently on attempts at motion. The flesh and strength returned in the left leg in perhaps two years, though the patient has noticed ever since the war that motion was not so strong in the left as in the right limb, and that the toe is inclined to drop in walking. He complains now of no pain anywhere, but of occasional "drawing" and "crawling" sensations in the back of left leg, numbness in the left hand and fore-arm, and sometimes a sensation of being struck in the back. No shooting pains, never saw double, no gastric symptoms, never head-ache. Occasional attacks, of short duration, of dizziness with tendency to whirl round (he does not know in what direction), nausea, and buzzing in the left ear. Patient is much more irritable than before the war, but shows no loss of memory or power of concentration. There is a history of loss of sexual desire and power dating from time of the war. He has noticed ever since that time that the strength of the left arm, formerly nearly or quite as good as that of right, is much impaired. Patient denies venereal infection, even gonorrhœa, and says that he has never been subject to sore throat, and has neither had eruption on his body, nor falling out of hair. He relates

that while soldering about two years ago some of the hot solder ran through the fly of his pants and burned the back of his penis. The only history of severe injury to be elicited, other than the explosion, is that some months after leaving the hospital in 1862 he was struck on the head by a freight train drawn by mules. He was knocked down, somewhat stunned, but was able to get upon the car. Recovery said to be rapid, and without nervous or other symptoms.

Physical examination. The patient is a short stout man of intelligent mien and good muscular development, excepting that all the muscles of the left arm are decidedly smaller and less resistant than those of the right.

On the scalp exists a cicatrix high up in the occipital region a little to the left of the median line. This cicatrix is broadly linear, two and one half centimetres in length, non-adherent, non-sensitive, and shows no loss of substance. On the dorsum of the penis, well back from the glans, appears a superficial white oblong cicatrix, 0.7 centimetre in length.

The cicatrices representing the course of the shot received in the thigh are as follows: a horizontally linear cicatrix 2.5 centimetres in length, situated at the outer extremity of the fold of the left buttock, and showing considerable loss of substance; a horizontally linear cicatrix 1.5 centimetres long on the inner side of anterior surface of the left thigh, opposite the scrotum, representing considerable loss of substance, quite sensitive, pressure on it causing tingling sensations down the leg; a linear cicatrix four centimetres in length on the outside of the left scrotum, running downwards and inwards from a point opposite the cicatrix on the thigh, and forked at its upper end; a small cicatrix in the posterior perineal region (where the ball was extracted).

No enlarged glands found. The pupils are of average size, alike, and react both to light and to (attempts at) accommodation. The patient's gait is somewhat uncertain on account of blindness, but is not ataxic; the only peculiarity noticed is a slight tendency to scrape the left toe in walking.

Motion. No ataxia. On testing the strength of the various muscles all muscles on the right side prove very strong, those of the left arm and leg only fairly so. The grasp as measured by the dynamometer bears the relation of (left) 22 to (right) 40, repeated trials giving the same result.

Measurements of the upper arm show (right) 30.5 centimetres, (left) 29.5 centimetres. Fore-arm (right) 27.5 centimetres, (left) 26 centimetres. Calf (right) 33.5 centimetres, (left) 33.5 centimetres. Reactions to the faradic current, strong on the right, are lessened on the left. Patellar reflex is increased on both sides, especially on the left.

Sensation. All forms of sensation are markedly diminished on the entire left side to the median line, with the exception of an area over the abdomen bounded above by the line of the ribs, below by Poupart's ligament, and outwardly by the axillary line (the line of demarkation is quite sharp, but the above is only an approximate description of its situation). The diminution of sensation is somewhat less on the head and face than on the trunk, but is bounded here also sharply by the median line. A pin can be thrust through a fold of the skin on the left leg without causing the least pain, and only strong pressure is perceived at all. All attempts to surprise the patient by painful stimuli over the anæsthetic area prove futile.

Special sensations. The senses of *smell* and *taste*, normal on the right, are entirely absent on the left. The general anæsthesia is marked on the inside of the mouth, and pinching of the left side of the tongue is not felt. The left side of the tongue shows signs of having been severely bitten (probably due to the anæsthesia, the patient stating that he finds himself very awkward in the mastication of his food on the left side).

Sight. The patient can only distinguish light from darkness.

Hearing. On the right absent for all sounds both by air and bone. On the left greatly impaired for all sounds by the air. Low voice only heard at one foot. All tones heard equally well up to 35,000 vibrations (König's rods). The tuning-fork on the teeth is heard only on the left. A large tuning-fork placed on the left mastoid bone is heard with difficulty even with the ear shut (indicating defective hearing for sounds through the bone on the left).

Examination of the eyes by Dr. Bradford shows white atrophy of both disks.

Examination of the ears by Dr. Spear shows old purulent inflammation of both middle ears, with cicatricial healing of the membranes.

This case, though not coming under the head of those commonly classed under "railway spine," is interesting in this connection as illustrating the fact that a distinctly hysterical hemianæsthesia may follow cerebral concussion. There seems no other plausible way of explaining the symptoms excepting through injury by shock, as there is nothing in the patient's antecedents or in his own temperament previous to the injury to lead to a suspicion of simple hysteria, a disease of great rarity in the male. The supposition of cerebral hæmorrhage or tumor as causing this set of symptoms, involving equally all sensory and motor functions of one side of the body, is improbable in the extreme, while the impairment of these functions is so characteristic of hysteria as to render this the only probable explanation. The complete deafness in the right ear and the complete blindness, although probably also resulting from the injury, must be looked on as extraneous to the hysteria.

With regard to the hearing. The immediate result of the concussion from the bursting of the shell was probably the rupture of both drumheads, and the starting of an inflammation in both middle ears. The absolute deafness by the bone on the right renders it not improbable that still further lesion of the auditory structures took place, perhaps a hæmorrhage into the inner ear. The deafness in the left ear is about that which would naturally result from a purulent inflammation, excepting, perhaps, the slight deafness by the bone. Whether this is due to the inflammation, to the hysteria, or to deeper lesion, similar to that on the right, it is impossible to determine, but the latter seems eliminated by the fact that all tones are heard up to 35,000 vibrations.

The blindness (which is so excessive as to mask the amblyopia characteristic of hysteria which would have been expected on the left) is of course due to the atrophy of the optic nerves, a result of cerebral concussion not without precedent.¹ That this atrophy is

¹ Erichsen (Concussion of the Spine, 1875, page 236) says: "If such serious organic mischief can declare itself in the interior of the globe as a consequence of a general jar or shake of the head, it is not unreasonable to suppose that in many of those cases that we witness, in which, after a general shock to the system, obscuration

due to an attack of typhoid fever from which the patient suffered two years ago is negatived by the fact that atrophy was diagnosed at the Eye and Ear Infirmary previous to that sickness. The fact that this patient was a claimant for legal restitution can have but little influence on the genuineness of the symptoms. In the first place the hysterical symptoms were not at all essential to his claim, and in the second place they were so absolutely typical of a disease as yet little known, even amongst the medical profession, as almost to preclude simulation, to say nothing of the repeated unsuccessful attempts to expose deceit.

The fact being tolerably well established that the patient's condition results from injury, it is not important for us to discuss the question whether the accident on the railway or the explosion of the shell was the ætiological factor. The apparent greater severity of the latter shock, together with the fact that the deafness and other symptoms, as far as can be learned, dated rather from the time of the explosion, seems, however, to throw the weight of evidence in favor of that accident.

With regard to the question of syphilis, there is no way of deciding absolutely whether the alleged is the real cause of the cicatrix on the penis, but in the absence of other symptoms we have no right to assume that this disease exists, because of the cicatrix.

THE NEGATIVE ARTERIAL PULSE.

BY A. T. KEYS, M. D.

THE object of this communication is to present the negative arterial pulse. With the positive arterial pulse all are familiar, but the idea of a negative pulse of the arteries, so far as I can learn, has not hitherto been advanced.

First in 1874, when tracing with Marey's sphygmograph the radial pulse of a boy affected with disease of the heart, I obtained a distinct inverted trace, which I then interpreted as of pathological significance. Subsequently, in practicing with my own instrument, I have constantly encountered this phenomenon, and have come to learn that it is the negative arterial pulse, normally existing, and revealed in an inverted trace when the instrument is applied to the artery in a particular way.

The negative pulse may be demonstrated in all the larger superficial arteries by placing the explorer closely by the side of the artery instead of directly

upon it, as when the ordinary positive trace is obtained. The negative trace, compared with the positive, is inverted and of smaller amplitude, and presents more distinctly the smaller secondary waves (those occurring during the time of closure of the sigmoid valves); also

FIG. 1.

FIG. 2.

its respiratory undulations are more marked, and usually the trace is best taken at a lower pressure. It corresponds with the positive in general form, in the number and relative position of the secondary waves, in the aortic notch, and is exactly synchronous with it in primary start and each individual phase throughout. In demonstration of these statements the accompanying figures of traces are given.

Fig. 1 shows the carotid, negative and positive. Fig. 2 shows the radial, positive and negative. Fig. 3 shows the dorsalis pedis, positive and negative. And Fig. 4 shows the same carotid positive and negative, taken simultaneously. These traces speak for themselves; with regard, however, to Fig. 4 a word of explanation may be added. To obtain the two kinds of traces from the same carotid simultaneously required a particular adjustment of the explorers, which was found

FIG. 3.

FIG. 4.

only after repeated trials. The vertical lines cutting the traces were made by the writing levers respectively with the slide at rest; and, cutting the traces as they do, they demonstrate the exact synchronism between the negative and positive pulses.

MECHANISM OF THE NEGATIVE ARTERIAL PULSE.

The mode of production of the negative arterial trace has been to me a puzzling problem, but I believe now its solution is found in the locomotion of the arte-

and impairment of vision gradually manifest themselves, and in which white atrophy of the optic disk is discovered by ophthalmoscopic examination, the injury to the eye, functional and organic, is due to a shake or jar of its nervous structures, by which their nutrition becomes seriously but slowly impaired, and organic changes become secondarily developed in them."

ries. With each cardiac systole the arteries, in addition to expansive movements, rise *en masses* from their beds, and with each cardiac diastole they, in addition to retractile movements, fall back to their beds. This change of place must occasion a pushing out of the tissues over the spot towards which the artery moves, and a simultaneous drawing in of the tissues over the spot from which it moves. The locomotion will be in the direction of least resistance, and in the case of superficial arteries is likely to be to one side as well as forwards. If a visible superficial pulse, notably the radial, be watched, the artery appears to roll to one side in systole and fall back in diastole; the contiguous integuments simultaneously rising at one spot and falling at another.

Now if the explorer be placed fairly over the artery it receives the force of the locomotion as well as the expansion, and so is pushed up in systole, causing to be registered the positive arterial pulse; whereas if the explorer be placed by the side of the artery over the spot from which the latter moves in systole it is affected by an aspiration, and so is drawn down in systole, causing to be registered the negative arterial pulse. Moreover, impingement of the instrument in this situation tends to facilitate the arterial displacement. The positive trace falls in diastole in consequence of emptying and retreat of the artery, while the negative rises in diastole in consequence of return of the artery to its apposition with the explorer. The secondary waves of the negative traces are the same as in the positive, because the delicate contact of the explorer is sufficient to receive their impression as transmitted along the artery; and the small diastolic waves are more distinct in the negative because the lighter pressure is more favorable for their reflection, the pressure in the case of the positive trace almost, if not quite, obliterating the arterial lumen in diastole. Also, for the same reason (lighter compression of the artery), the respiratory undulations are more marked in the negative line.

The characteristics given unmistakably stamp the trace under consideration as of arterial origin. The negative venous trace, where obtainable, differs essentially from this in form and in chronometry; besides the vein would be effectually collapsed by the pressure employed to develop this trace.

The demonstration of the negative arterial pulse adds an interesting fact to our knowledge of the physiology of the pulsations, and one whose utility is already apparent, in that its recognition will relieve the study of the negative venous pulse from a source of confusion in fact seriously encountered.

THE NEGATIVE CARDIAC TRACE.

This is a proper place to allude to the negative trace of the pulsations of the heart, a phenomenon already recognised, but whose explanation has not been entirely satisfactory.

The negative cardiac trace is usually of less amplitude than the positive, although in some cases it equals or even exceeds it, and in some again only the negative can be obtained. Its main descent begins synchronously with the main ascent of the positive, and it marks the same duration of systole and diastole;

the secondary waves also correspond in number and position with those of the positive.

Fig. 5 shows simultaneous traces of the same heart, taken both positively and negatively. The vertical lines show the synchronism between the traces.

With regard to the mechanism of production I believe it is similar to that of the negative arterial,

FIG. 5.

namely, by a rhythmical locomotion of the organ. With a certain position of the explorer the heart glides or rolls from under it in systole and returns to it in diastole, causing the negative trace; whereas when the explorer is placed fairly over the spot of greatest positive impulse the heart presses it in systole and remits the pressure in diastole, causing the positive trace. Cardiac aspiration from reduction of volume, although conceivable as a possible factor, does not of itself afford a sufficient explanation, for cardiac reduction of volume can only begin a notable time after the beginning of systole, whereas the negative cardiac trace begins, as demonstrated, synchronously with systole.

THE MANAGEMENT OF PATIENTS DURING CAPITAL OPERATIONS.¹

BY GEORGE W. GAY, M. D.

THE object of this paper is to call attention to the management of patients while they are undergoing severe and critical operations. As it is oftentimes the little things which tell in these cases, and which go far toward deciding the result, we shall dwell especially upon their importance, and hope not to be thought trivial in so doing.

A brief narration of three cases which have lately been under our care at the Boston City Hospital will illustrate our ideas upon the subject much better than would any abstract remarks.

CASE I. While walking upon the sidewalk, March 17, 1883, Mr. S., aged fifty-two years, was thrown into the air by an explosion of ignited gas in an adjacent cellar, and fell into the excavation amidst paving stones, bricks, and other debris. Having been brought to the hospital within an hour of the accident, he was found to have sustained a compound comminuted fracture of the left tibia into the knee-joint. The leg was enormously swollen, tense, blue, and cold, and there was no pulsation in the tibial arteries. Above the knee was a large, ragged wound extending deeply into the bruised tissues of the thigh.

The patient had evidently lost considerable blood from subcutaneous hemorrhage, and he was in a partial collapse. He was conscious, but restless; pulse weak and rapid; skin pale and cold.

Nothing whatever was given by the mouth, as a

¹ Read before the Boston Society for Medical Improvement, June 11, 1883.

pretty extensive accident-room experience has proved to us that food and stimulants poured into the stomach of a person while in collapse do no good, but on the contrary sooner or later produce vomiting, and thereby increase the prostration. A stimulant dose of morphine (one eighth of a grain) was given subcutaneously, and warm injections of brandy and water were given by the rectum. He was surrounded with heaters, covered with blankets and a rubber sheet, and kept as quiet as possible.

In an hour or two the patient had rallied sufficiently in our opinion to undergo a rapid amputation of the thigh. Everything being in readiness a little ether was given, and at the earliest possible moment the limb was quickly removed by transfixion at the junction of the lower and middle thirds. As soon as the bone was divided the anæsthetic was taken away, and no more was given. The result was that the patient was unconscious but a few moments, and regained his senses long before the vessels were secured and the stump was dressed. There was very little additional shock resulting from the operation, and the vomiting was unimportant.

The treatment pursued before the operation was continued for several hours after it, when small quantities of milk punch were given by the stomach and retained, and the question of nourishment gave us no more trouble. Omitting all details of the convalescence, suffice it to say that the patient made a good recovery.

CASE II. Thomas G., an expressman, twenty-two years of age, was brought to the hospital January 11, 1883, suffering from a large sarcomatous tumor of the left thigh. The disease was of six months' duration, and began as a small, tender bunch over the internal condyle of the femur.

When first seen by us it involved the lower half of the thigh, and was discharging large quantities of a dirty, sanious fluid. The glands below Poupart's ligament were slightly enlarged, but the abdominal cavity was apparently free from disease.

The patient was in a state of extreme exhaustion. Pulse 150. Temperature 103° F. Pale and emaciated, but there was no cough, vomiting, nor diarrhoea. It having been explained to him that an amputation, though attended with danger, was the only measure that promised relief to his suffering or could prolong his life, he requested that it should be done. For a few days efforts were made to improve his condition by means of liquid food, stimulants, tincture of digitalis, and tincture of nux vomica.

When ready for operation he was brought from the ward in his own bed, surrounded by heaters and covered with blankets and a rubber sheet. A very little ether having been given he was quickly transferred to the operating table, still covered up warmly, and the thigh was amputated as rapidly as possible by the circular method at the middle third. The ether was at once stopped, not over three ounces having been used, and in three minutes the patient was conscious. There was almost no shock from the operation, no vomiting, and in twenty-four hours the temperature was normal, and the patient "felt better than he had for months."

During convalescence he was free from pain, ate heartily, and grew fat. The wound healed kindly, with the exception of a small spot over the end of the femur, which became pale and cedematous, and looked like the original disease. The glands in the groin also began to enlarge.

Five weeks after the amputation a second operation was done for the purpose of removing the remainder of the femur. A long incision was made on the outer surface of the stump, the head of the femur disarticulated, and the bone carefully dissected out. The operation was necessarily of considerable length, the hæmorrhage was pretty free, and the shock was marked.

The contrast in the effect upon the patient of the two operations was very characteristic. In the first instance, although he was in a miserable condition, yet after a severe but quick operation he rallied almost instantly, while in the second case he was in a comparatively good condition, and yet after a prolonged operation the prostration was very severe. He finally rallied however, and got nearly well, when he was seized with pleuro-pneumonia, and died in a week.

CASE III. R. H., conductor, about twenty-seven years of age, was run over by a horse-car January 19, 1883, and received a compound fracture of the left tibia and fibula at the lower part of the middle third. The line of fracture was very oblique, and the tissues were considerably bruised.

Treatment consisted in placing the limb in a "plaster posterior" splint, and applying compound tincture of benzoin under carbolized gauze. Profuse suppuration and necrosis followed, and after several weeks the fragments were carefully adjusted and wired together.

In spite of all our efforts the patient gradually failed, and all hopes of saving the limb were abandoned. The pulse was rapid and feeble, the temperature was high; he was pale and emaciated, and suffered from chills, sweats, and great irritability of the nervous system, being delirious at night; his appetite was poor, but there was no vomiting nor diarrhoea.

It was evident that an amputation of the leg was the only means which could save his life, but it was the general opinion of the surgeons who saw him in consultation that he would not survive the operation over thirty-six hours.

A rapid amputation was completed March 18th under the same precautions as were used in the last case. The utmost care was taken to prevent shock and exhaustion by saving as much time, blood, and animal heat as possible. The result was all that could have been desired. The patient rallied well from the anæsthetic a few moments after the leg was removed, and his temperature fell five degrees inside of twenty-four hours. Convalescence was rapid, and the stump was healed in a fortnight.

The idea pretty generally prevails that in these days of anæsthetics time is of little or no consequence in doing capital operations. I do not accept this view of the matter. Experience has taught me that in the class of cases under consideration the more quickly the operation is completed, and the earlier the patient is allowed to rally from the anæsthetic, the less will be the subsequent shock and exhaustion. This fact is particularly noticeable in children, in whom a temporary collapse is not uncommon after a severe or a prolonged operation. There can be no doubt that a long operation is debilitating to the nervous system of any one, even when it is done without pain or without the loss of much blood.

It is claimed by some that as sulphuric ether is a powerful stimulant when injected under the skin, its inhalation is therefore beneficial in cases of great prostration requiring an operation. While the primary effects of this agent when inhaled are stimulating, the

ultimate result has seemed to us to be depressing, and especially so in those persons prostrated by injury or disease.

Usually the pain experienced by patients in the later stages of an operation is not detrimental. It is momentary, and soon forgotten, as they are still somewhat dazed by the anæsthetic. An opiate given previous to the operation also tends to allay suffering and produce quiet. Moreover, the pain seems to be less severe toward the close of an operation than it is at the commencement. Every surgeon must have noticed this fact in connection with operations about the face, when it is oftentimes not practicable to keep the person completely under the anæsthetic. Fear and dread are to a great degree absent when an operation is well under way.

These facts have led me to remove the anæsthetic at a much earlier stage in many operations than is the general custom, and I think with beneficial results to the patients.

In concluding we would urge that special attention be paid to the following particulars while doing critical or capital operations:—

If shock or collapse be present put nothing into the stomach, but stimulate and nourish by the skin and rectum.

Take extra pains to keep the patient warm by means of heaters, blankets, and a rubber sheet.

Disturb him as little as possible with examinations, moving, changing of clothes, or dressings, etc.

Use the least possible quantity of the anæsthetic, and allow the patient to rally early, depending upon opiates to control subsequent pain and inquietude.

Finish the operation as quickly as is compatible with its proper performance.

Get the patient into a warmed bed as soon as possible, and without any exposure to cold.

Preserve the utmost quiet, and avoid doing too much for the patient until fair reaction has taken place.

By observing these precautions we are confident that in more than one instance recovery has taken place, in which by neglecting them the result would have been fatal.

THE HYGIENE OF THE LYING-IN ROOM.¹

BY FRANCIS MINOT, M. D.

In a valuable paper lately read before this Society, Dr. Reynolds pointed out the advantage of visiting patients previous to their confinement, with the view of obtaining a knowledge of their general health, and of the presence or absence of symptoms which might indicate the possibility of grave complications during and after labor. Among other things he suggested the propriety of making an examination of the urine should there be any reason to suspect renal disease. It has occurred to me that a visit to the apartment in which the woman is to be confined is equally important, in order to ascertain, if possible, its sanitary condition (and also that of the house itself), and to remedy any existing defects which might be prejudicial to her health. I have reported to the Society some cases in which I believe that serious disease, and even death, occurred in the puerperal state from defective sanitary

conditions which might have been obviated if proper precautions had been taken. No surgeon would now undertake a serious operation, such as ovariectomy, without a preliminary survey of the house, as well as of the room in which it was to be performed. Women in the puerperal condition are peculiarly sensitive to the influence of bad drainage and imperfect ventilation, and in modern lying-in hospitals every effort is made to protect patients from these evils. It is somewhat remarkable that so little attention is paid to the hygiene of the lying-in room in private dwellings. It is well known that the drainage and plumbing of a great many houses are defective, allowing a more or less ready access of sewer gas to their interiors, and sometimes giving rise to typhoid fever, diphtheria, scarlatina, and other diseases. It is time that our attention should be awakened to the danger of this poison in the lying-in room. In anticipation of the confinement, it would be wise if an examination of the condition of the drainage and plumbing of the house should be made by an expert in every case in which its integrity had not been already ascertained, in order that any existing defects might be remedied.

The lying-in room should be large, if possible should face the south, and should be provided with an open fire-place which will not smoke. It should not have a "set basin," or other convenience connected with a drain, and it should not communicate by a door with another room containing a water-closet, bath-tub, or set basin; or, if this be inevitable, paper should be pasted over all the edges of the door and key-hole, on both sides, and the door should be kept locked. If a room containing a set basin must be occupied by the patient, it is well to have the waste pipe cut off, and the lower end sealed by the plumber, a pail being placed beneath the basin to receive the waste-water. An examination of the gas-fixtures should also be made to insure against the escape of illuminating gas into the room, a very frequent occurrence, not only in hotels and lodging houses, but also in private dwellings. The wall paper should also be inspected, and tested for arsenic, if need be. The room should be thoroughly swept and cleaned before the period of confinement, and all useless furniture be removed, as well as the numerous ornaments, books, work-baskets, etc., which are apt to encumber the tables and mantel-piece to the inconvenience of the attendants of the patient. Ether and a sufficient supply of a solution of carbolic acid should be provided, as well as an abundance of towels, sheets, etc.

Whenever the weather is so cool that the room is uncomfortable with an open window, a fire should be kept constantly burning in the fire-place during the period of lying-in. The fuel, if possible, should be wood or cannel-coal. Even in warm weather, if the ventilation of the room be not satisfactory, it is well to have a kerosene lamp, or a portable gas jet, connected by a flexible tube with a gas bracket, kept burning in the chimney. Except in very cold weather, a window should always be left open, at least sufficiently to allow some air to enter; in many cases it is enough to raise the lower sash a little, so as to admit a current above it.

Women are usually delivered on a large double bed, which is sometimes so low as to cause much fatigue to the attendants. The patient, especially while under ether, often becomes unmanageable in the middle of it, beyond the reach of the doctor and the nurse. The

¹ Read before the Obstetrical Society of Boston, November 11, 1882.

lying-in bed should be a single one, three and a half feet wide, and the top of the mattress should be two and a half feet from the ground. The patient is then perfectly under control; all necessary obstetrical operations can be performed to the best advantage, and the nurse's duties are rendered much easier. During the whole of the patient's illness she should lie on the same bed, where she can be made far more comfortable than on a larger one, owing to the greater facilities it offers for her toilet. A foot bath-tub, or other vessel, should be provided to receive all soiled napkins, dressings, etc., to be immediately afterwards removed from the room and disinfected. If the catheter be required, the instrument, when not in use, should be kept in a disinfecting solution. No food or article of diet should remain in the sick room, except liquids which are required to be given to the patient at short intervals.

I am aware that in some cases opposition might be raised to the carrying out of the above details, even when their execution would require but little trouble or expense, but I conceive it to be the duty of a physician who is engaged to attend an obstetrical case to suggest their importance, and to point out the danger which experience has shown may follow their neglect.

AN INTERESTING CASE OF FEMORAL HERNIA IN AN AGED PATIENT; STRANGULATION; OPERATION, WITH CURE.¹

BY WM. R. D. BLACKWOOD, M. D.,
Neurologist and Electrician to Presbyterian Hospital, Physician to St. Mary's Hospital.

MR. B., aged seventy-three, tall, thin, but bearing his years well, and with a previous history of good health, was taken ill with supposed cholera morbus on Saturday, August 11, 1883, but from the suppression of alvine dejections shortly after the seizure, and the rapid change of the vomited matter to a manifest stercoraceous fluid by the time his family physician, Dr. John Iverson, saw him, the diagnosis of the family was set aside for one of more grave nature. The gastric distress was very great, the desire to vomit urgent, and the act occurred at short intervals. Previously to his illness the gentleman had been extremely constipated, and the amount of liquid and semi-solid fecal matter rejected per oram was simply inconceivable except to those who saw it. At each instance of vomiting, a fair sized wash-basin was half filled, and the total quantity thrown up before relief ensued was, to speak within bounds, fully three gallons, showing the enormous distention of the intestine which may occur in chronic constipation.

The case was believed to be one of obstruction, with possible invagination of the bowel, and efforts were made toward overcoming the difficulty and obtaining an operation in a normal direction, but without success. The question of strangulation by hernia was not at first accepted, because, although there existed an evident swelling at Poupart's ligament, the size of it was so small as to be taken for an enlarged gland, the patient having had glandular enlargement previously. There was no local pain, no tenderness, no tension, no dragging sensation at the site of the swelling, no tympanites, — in short, the usual local signs of strangulated hernia were absent. The little tumor also was movable

to such an extent as to easily deceive one, even when closely examined. The doctor having asked my opinion as to the condition of the patient, we saw him together, and I coincided with him as to the difficulty in stating positively to the family the evidence of hernial strangulation, but as the patient was rapidly sinking from exhaustion, we decided to make an exploratory incision and determine the nature of the enlargement, the justice of this being explained.

The patient was etherized, and after cutting down to the sac the mass was found to be an entero-spirocele. The sac contained very little serum, and considering the fact that strangulation had doubtless existed for at least thirty-six hours, the bowel, though highly congested, was in good condition. The gut was tightly nipped at the crural ring and was nearly empty, which accounted for the small size of the tumor. The hernia was internal to the femoral vessels, but closely adherent to them. It was reduced with some difficulty and pushed far up to clear the deep thrust of the needle in closing the wound. The sutures, four in number, were deeply taken and the ring obliterated as nearly as possible. A compress of lint, wet with a mixture of Canada turpentine, oil of sweet almonds, carbolic acid, and glycerine (an excellent dressing), was applied under a spica bandage of the groin, and the patient made comfortable in bed. He reacted well from the operation, vomited freely once thereafter, and in an hour and a half passed an alvine dejection without pain or difficulty. The appetite returned moderately at once, food was well retained, and his strength returned nicely. For forty-eight hours the wound did well, healing for one half its length by first intention, but then inflammatory action set in and free suppuration ensued. In a week, however, the wound had closed, and the old gentleman was able to walk his room with comfort.

The diagnosis of femoral hernia is, at times, not easy, being, as here, liable to be confounded with enlarged glands or localized varix of the saphena. There was no impulse on coughing, no effort at reduction affected it, and excepting only the very small tumor, all the local signs of strangulated gut were absent. The advanced age of the patient was against him, and his depressed vital power was a bad factor. The result shows the value of exploratory operation under the circumstances, and I believe that the attendant is unfaithful to his patient if he does not insist upon it in every suspicious case. The wound is of little account, — it does not enhance the danger which is already imminent, and it may, as here, save a valuable life.

REPORT ON PROGRESS IN SURGERY OF DEFORMITIES AND DISEASES OF JOINTS.

BY E. H. BRADFORD, M. D.

RESECTION OF THE ASTRAGALUS IN ANKLE-JOINT DISEASE.

P. YOGT² advises when resection is indicated in disease of the ankle to begin by excision of the astragalus without removing the malleoli. Two incisions are made, one long anterior, and the other a short lateral cross incision. Langenbeck's method has been the one usually adopted, and consists of bilateral cuts, and a removal of a portion of the tibia and fibula

¹ Read before the Philadelphia County Medical Society, September 19, 1883

² Centralblatt f. Chirurgie, xix., 1883.

for a thorough inspection of the joint. Experience, however, has shown that the astragalus and the neighboring tissues are the parts most involved in the disease both in chronic synovitis with secondary destructive change and in primary osteitis, while the bones of the leg are but slightly affected. Hueter¹ has advised the cross incision recommended by Sedillot and Heyfelder, dividing tendons as well as all soft parts, and thus allowing a full view of the joint. This, of course, divides the tendons and nerves, and, as the writer justly remarks, should be regarded rather as a technical experiment than an accepted procedure. Busch recommends also an incision which should be classed among the surgical curiosities, namely, a cut through the sole from malleolus to malleolus similar to that in Syme's amputation, and a division with the saw through the os calcis, and the opening of the ankle-joint from below.

Vogt proceeds as follows: The skin and soft parts are divided to the bone in a line on the front of the foot extending from the junction of the tibia and fibula to below the line of the medio-tarsal articulation, that is, the line of Chopart's amputation; the tendons, etc., are pushed and drawn aside, the capsule of the joint opened, and the ligaments and periosteum as far as possible pushed aside by means of an elevator, the head and neck of the astragalus laid bare on the upper and outer surface. A lateral cross incision is then made extending to a point below the external malleolus. The ligaments binding the astragalus are divided, and the bone removed by means of bone forceps and chisel or elevator. The whole synovial membrane can be seen, and any diseased portion easily curetted. A drainage tube is then inserted, and the foot placed in position.

LAXITY OF LIGAMENTS OF THE JOINTS IN RICKETS.²

Kassowitz explains this symptom by the supposition that the vascularization of the spongy tissue of rickety bones extends to the perichondrium. Each vessel in the sub-cartilaginous fibrous sheath is surrounded by a zone of embryonic tissue, and the fibrous fasciæ as well are seats of cellular proliferation. The periosteum presents similar changes, and these are most marked at the points of insertion of the capsule and articular ligaments, which, being intimately connected with the periosteum, and also the perichondrium and the bone, are involved in the rachitic process, and lose their power of resistance. Force acting mechanically under these conditions leads to a stretching of these ligaments and a permanent relaxation. This stretching of these ligaments is painful, and Kassowitz is of the opinion that it is this pain rather than muscular weakness which causes the difficulty rachitic children encounter in walking.

THE SECONDARY CHANGES IN MUSCULAR TORTICOLLIS.³

Witzel has had an opportunity to examine by dissection a cadaver in which during life the deformity of wry neck persisted for a long period. The anatomical knowledge on the subject hitherto gained by dissection is small, although anatomists as far back as Tulpus

have interested themselves in the subject, and recorded their observations. Witzel's observations were made with great care, and deserve publicity. The deformity in the case dissected had persisted for forty-four years, and was pronounced in character, and congenital in its origin. The convexity of the skull was somewhat flatter on the right (the elevated) side than on the left, and the same was true of the brain. The cervical vertebræ were found curved, with convexity toward the right, and the trachea was dislocated somewhat toward the concavity. The right sterno-mastoid was a broad, flat band, while the left was a short, round, fibrinous cord, and the symmetrical course of the large vessels normally seen was not found. The spine presented a well-marked scoliosis, with the convexity to the left in the dorsal, and to the right in the lumbar, region, and the pelvis was twisted, the right side being lower and farther back than the left. The cervical vertebræ were found rotated, but the ligaments between the several vertebræ and the head were not changed except that their length and position fitted the position of the head.

The intervertebral substances were thicker on the convex side than on the concave, and this, but to a more marked degree, was true of the articulations. The same asymmetry was found in all the vertebræ, varying as to the distorted side in the different parts of the column. Marked lack of symmetry was to be seen in the skull. This was more marked in the facial bones than at the back of the skull. The middle line of the skull, seen from below, formed a curve, the face being turned to the right relatively to the axis of the rest of the skull. The shape of the face was altered in a characteristic way, the right side being higher and narrower than the left. The lower jaw also was twisted to the left, and slightly backwards.

The distortion of the pelvis was precisely that which is described as characteristic of the rachitic-scoliotic pelvis, except that no evidence of rickets could be seen; that is, the promontory was not pushed forward and the foramina were not flattened, but the right side of the pelvis was lowered and turned to the right, and the lumbar lordosis was more marked than is normal.

The muscles were so gangrenous and cedematous that exact results in comparison could not be obtained. The value of these facts with reference to the theory of muscular traction is pointed out by the writer. Dieffenbach was of the opinion that the distortion of the face always seen in pronounced torticollis resulted from muscular tension. This view has been revived in later times by Albert, but he admits that it does not satisfactorily explain the facts. Bouvier thinks that the altered position of different parts of the body determined a difference in the amount of blood supply in the different sides, and hence a lack of symmetrical growth, and this theory has been accepted by Nélaton, Musson, Guérin, Broca, and most French writers. Little, in Holmes's System of Surgery, vol. iii., p. 591, suggests an explanation, and Busch⁴ is of the same opinion, namely, that the atrophy is due to the interference in the function of certain parts. The explanation which the writer considers on the whole as the most satisfactory is that the tension on the soft tissue in certain parts causes pressure, and in that way hinders development, hence atrophy results.

ARTHROPHYTES (LOOSE CARTILAGES) OF THE KNEE.

Poncet¹ states his opinion in favor of the belief in a traumatic origin of these bodies, although this opinion is not held by many surgeons. Certain cases cited by Richet, Bachelet, Boeckel, Chipault, and others support a belief in this mode of origin, and Poncet, after a number of experiments on cadavera, thinks there can be no doubt that this is the fact. Microscopical examination proves that there are two forms of traumatic floating bodies of the joint, one femoral or tibial according to their origin, the other, which being of capsular origin, does not contain structurally all the phases of transformation of tissue from fibrous to fibro-cartilaginous, cartilaginous and osseous. The osseous tissue, if it exists in the interior, does not form a central focus, but is a regular band extending to the border of the arthrophyte. A fibrous capsule of new formation may cover the torn osseous surface, but this envelope does not present the stages of evolution seen in the true arthrophyte, which arises from the synovial membrane. M. Poncet advises extraction as the only treatment, and under antiseptic precautions thinks well of the method.

ANGULAR ANCHYLOSIS AT THE HIP-JOINT.

Prof. Stephen Smith² reports a successful operation for the relief of this deformity, in which Shradys fenestrated saw was used. The advantage claimed for this instrument is that it is impossible for the point to injure deep tissues in the process of sawing. The saw blade works inside of a fenestrated canula, the fenestrum being large enough to allow the saw to cut when moved in and out of the canula. The process is a slower one than that with the ordinary saw. Smith recommends dividing the bone nearly through at two adjacent points, — one on the anterior, and the other on the posterior, surface of the femur; the bone is to be then fractured, and a mortise is thus made which serves the purpose of holding the bone in better position than is the case after complete division of the bone.

PROGRESSIVE OSSIFYING MYOSITIS.

Kümmell³ considers this affection not merely a pathological curiosity, but a well-defined disease, the etiology and nature of which have not yet been thoroughly studied. He reports one case, and has only been able to find in the literature an account of twenty-four others. In the writer's case the trouble appeared to be of congenital origin, as at the time of birth a noticeable deformity of the back was observed, and a limitation of the mobility of the shoulder-joints, and a deformity of great toes. When the child was two years old he suffered from a febrile attack, and there appeared upon the back several tumors, at first soft, but which afterwards became hard. The disease progressed gradually and imperceptibly, not influenced by an attack of scarlet fever, the only sickness the child suffered from, until the twelfth year of his age, when he became noticeably worse. The general nutrition was good; the patient was thoroughly intelligent and well, except in respect to the power of motion. The head of the patient was inclined forwards, and slightly to the right, the humerus could be moved but slightly from the thorax, and the trunk was held in a

stooping position. The head was of normal shape, with rather a prominent forehead, and a protuberance of the size of a hazel-nut was to be seen over the back part of the parietal region. Movements of the head were possible only to a limited degree in a vertical direction or in rotation. Motions of the mouth and tongue, as well as the muscles of the face, were free, but a hard mass connected with the hyoid bone, the thyroid cartilage, and the upper part of the trachea, could be felt. The sterno-cleido-mastoid muscles had degenerated in both portions to a tight fibrous band, and the sterno-hyoid was also to be seen as having undergone a fibrous degeneration. The neck was bent forward, and moved as if it was formed of one solid mass, and a bony projection, apparently slightly movable, could be felt to the left of the fifth cervical spinous process. The thorax was misshapen, the breast bone being prominent, and the pectoral muscles presented several bony masses in the substance of the muscle. The respiration was chiefly abdominal, though the chest expanded 2.5 centimetres at the height of the nipple. Rotation of the humerus in the socket was free, but motion in the direction of abduction or forwards and backwards is limited by bony growth around the joint. A bony protuberance of the size of a hen's egg was to be felt in the left axilla. The abdominal muscles were normal, but on deep narcosis the psoas muscles could be felt as converted into a tough, hard mass. The back was twisted so as to present a scoliosis with the lumbar convexity to the left; several large bony masses were found prominent in the back; some apparently outgrowths from the spinous processes, and some in the belly of muscles. The scapulæ are only slightly movable. The thighs were slightly flexed, and at the upper insertion of the biceps was a hard tumor apparently not bony. The slight contraction of the knees was present, but both that and the flexion of the thighs were corrected by extension. A portion of the bony growth around the shoulder was removed under antiseptic precautions, giving an increase of the amount of motion in the direction of abduction. The faradic electrical reaction of all the affected muscles was found diminished.

Partsch⁴ reports a similar case, that of a boy seventeen years of age, in which the clinical course of the affection was somewhat different. The first symptom dated from a fall when the patient was seven years of age, and which bruised the shoulder, causing a swelling, which eventually developed into a hard, bony mass; a stiffness in the muscles of the fore-arm on the other side followed, and three years later a tumor of the forehead subsequent to a bruise. The left masseter became stiff, undergoing osseous degeneration after an alveolar abscess, so that opening of the mouth became possible only to a limited degree. Other complications gradually appeared, such as exostoses of and bony formations in the scaleni, left clavicle, anchylosis of the different vertebrae. The lower extremities were nearly normal with the exception of a few exostoses in the region of the hip, but the arms were rather more useless. The thumbs and great toes exhibited congenital deformities.

Pathologically the process begins with a simple infiltration of intermuscular tissue, sometimes with the symptoms of pseudo-fluctuation; this stage is followed by a fibrinous induration, that is, a cellular hyperplasia with subsequent shrinkage of the muscle; finally os-

sification takes place. This latter occurs after initial oedema has subsided. The writer verified the fact by the microscopical examination of a portion removed from a patient that the change was not a calcification simply of the muscle, but the formation of true bony tissue, accompanied by covering cartilage in places. Virchow has named the morbid process an ossific diathesis, and considers it a hereditary or congenital predisposition. Münchmeyer, considering it inflammatory, calls it progressive myositis ossificans. Some of the tumors are true exostoses, and connected with some part of the skeleton, looking like bony stalactites, but other tumors are purely transformations of connective tissue.

The disease may progress usually symmetrically until almost all the muscles of the body are involved, beginning in the vertebra or the muscles of the back. Sometimes an unusual form of congenital symmetrical deformity of the toes and fingers appears. Progress is made by progressive attacks occurring at long intervals. Treatment by baths, mercurials, iodide of potash, seemed to give only temporary benefit. The extirpation of such portions of bone as limited motion was not attended (in the case where it was attempted) by unfavorable results.

REFORMATION OF THE HEAD OF THE FEMUR AFTER EXCISION.¹

Küster reports two specimens obtained after excision of the hip from cases where he repeated the excision of the bone several months after the original operation. In the first instance the medulla cavity was not found closed in by bony formation, but in the second the appearance was very similar to that found in a diseased head of the femur. An apparent head and a partially formed trochanter were to be seen. The medullary canal was covered by a thin shell of bone.

Israel has published a case where the autopsy was made three and a half years after the operation of excision of the hip. The result had been a satisfactory one both as regards usefulness of the limb and mobility, and the examination showed that the normal type was reproduced, and that the thigh was united to the pelvis by a species of capsule. Histologically the cartilage was peripherally fibro-cartilage, but the nearer the bone the more it resembled true hyaline cartilage.

EXPERIENCE WITH PLASTER JACKETS.²

What has been termed the "plaster-jacket craze" has so far expended itself that there is danger that the advantages of the method be overlooked. The discussion in Berlin relative to the method is therefore of interest. Sonnenburg reports his experience in 205 cases (of which, however, only twenty-two were antero-posterior curves, the rest being lateral curvature). The jackets were applied on patients, were suspended from the head, but not the axillæ, the shoulders being free. The bandages were put on with moderate tightness forward and back, and pressure was made on the moist plaster by the hands of assistants. A renewal of the jacket was made in about six weeks, and after a while a leather corset was substituted, and gymnastics (in lateral curvature) employed. The reporter found correction of the curves to take place under light suspension in moderately severe and even

in some marked cases, and in the very obstinate curves some benefit appeared to be gained in the arrest of the progress of the disease. Felt and leather corsets in progressing disease Sonnenburg did not advise in early stages. Küster also found jackets of service in lateral curvature, and of use in caries, in which Sonnenburg did not agree with him. Eulenberg, on theoretical grounds, is opposed to the use of the plaster dressing with suspension in caries of the spine.

THREE CASES OF JOINT-NEUROSIS.³

Lehman alludes to the scarcity of the literature on the subject. Wernher⁴ claimed a distinctly inflammatory origin of the nervous symptoms, and that suppuration could follow in the cases of so-called "nervous" coxalgia, but Esmarch in his Monograph,⁵ as well as the earlier writers, Stromeier, Brodie, and Barwell, believe in the true nervous nature of the symptoms. The disease is not a common one, Esmarch being able to collect only eighty cases recorded in the literature, and furthermore the variety of symptoms which may be classed under the head of this disease is so great as to make the diagnosis difficult. Lehmann mentions that a beginning neurosis can easily be mistaken for a commencing inflammatory process, especially when other nervous symptoms are present than those manifested locally, and when, as is sometimes the case, the limb is held fixed in an abnormal position. The clinical history of the case, the absence of evidence of alteration in the shape of the joint, and the intensity of the nervous symptoms often guide in diagnosis. The treatment in Lehman's cases consisted of gradual correction of distortion by moderate continued extension, and later systematic attempts at walking. Arsenic internally in one case was of possible benefit.

CASE OF PECULIAR ALTERATION OF THE SHOULDER-JOINT IN INFANTILE SYPHILIS.⁶

Troisier reports the following unusual clinical history, which, before death, was considered as an instance of syphilitic pseudo-paralysis, described by Parrot: A child, seven weeks old, was brought to the hospital with evidence of hereditary syphilis and a congenital hare-lip, which was operated on successfully when the child was twelve weeks old. The patient could not move the left arm, and if lifted, the arm would fall as an inert mass, but voluntary motion of the fingers and slight contraction of the biceps were possible. After death it was found that there was no alteration in the joint proper, but the epiphyseal cartilage was separated from the diaphysis by a layer resembling thickened pus, and on traction the epiphyses could be completely pulled away from the diaphyses in the femora. Several of the bones gave evidence of gelatiniform atrophy.

TREATMENT OF LATERAL CURVATURE WITHOUT APPLIANCES.⁷

Bernard, Roth, of London, an advocate of this method of treatment, describes the principles of treatment as follows: If the slightest osseous deformity be present, complete restoration to normal shape is impossible, but even severe cases of lateral curvature exist without

osseous deformity, and are capable of being temporarily restored to a normal position. A patient, however, with confirmed distortion, with or without osseous deformity, may have become so habituated to vicious positions that voluntary attempts at correction on his part rather increase than correct the deformity unless directed by the surgeon, and exercises of the spinal muscles are absolutely necessary for complete recovery; good positions should be assumed at all times, in sitting, by means of suitable chairs; moderate walking is beneficial, lying prone or supine is not curative; spinal supports, when the patient can by his own efforts assume a normal position, are useless or injurious; swinging by the head does not strengthen the spinal muscles. By avoiding all vicious positions, by good ones being shown and maintained, and suitable exercises carefully practiced, better and quicker results can be obtained than by any other method.

— An outbreak of epidemic nervous disorder among the girls at a religious school in Brittany is reported. Thirty-five out of fifty girls were attacked by a choreic disorder, and the school was ordered to be closed by the local authorities.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

PROPOSED CHANGES IN THE CONSTITUTION AND BY-LAWS.

HOSTILITIES in the "code war" were resumed with great activity in the Academy of Medicine at the first meeting after the summer vacation, which was held Thursday evening, October 4th. Previously to the meeting the President, Dr. Fordyce Barker, had sent to all the Fellows of the Academy a circular, in the course of which he says, "The question now to meet is, What measures can be taken to secure for the Academy a return of its prosperity? by which I mean a restoration of its fraternal harmony and good fellowship, a renewal of its active scientific work, and an increase of its funds for the growth of its library and the adequate support of its journal department. . . . It must be obvious to all that to attain this end we must make a new departure on certain questions, to which it is unnecessary to refer more definitely. There is an 'irrepressible conflict' of views and opinions, which cannot be settled by parliamentary tactics or a majority of votes, but must continue until in the progress of time the moral sentiment of the profession is crystallized in a public opinion which will have the force of law. No possible good can come from profitless and irritating discussions of these questions in the Academy of Medicine. It therefore seems to me of vital importance that now, in making a new departure, everything in relation to them should be buried in the past and forgotten. The next point to be secured is by such a change in our organic laws as to make it impossible that trouble and danger can ever occur again in the Academy. At our first meeting in October certain amendments to the Constitution and By-laws will be proposed for discussion, and at the following meeting they will be submitted to the vote of the Academy."

The proposed amendments involve the following changes: In the Constitution the existence of the committees on Medical Ethics and Medical Education is discontinued, and the following is substituted for the present Article VIII.: "The Academy reserves the right of discipline by admonition, suspension, or expulsion, by which all rights and privileges as a Fellow are forfeited, for violation of its By-laws or regulations, for unprofessional, ungentlemanly, or dishonorable conduct, and for public immorality and great crimes." This article now reads, "The Academy reserves the right of punishing violations of its regulations, or of its code of medical ethics, by reprimand, suspension, or expulsion, and will recognize no Fellow as a regular practitioner who has been expelled." Among the changes in the By-laws are certain modifications of those referring to the duties of the Council and the Committee on Admissions, and the total abolition of those referring to the committees on Ethics and Medical Education. In the former of these By-laws two of the sections read as follows: "Section 3. It shall be deemed a chargeable offense to countenance, encourage, or patronize — by advertising, giving certificates, or in any other way whatever — an irregular practitioner, or the proprietor or vender of any nostrum, patent or quack medicine, or to commit any act which unfavorably affects the character of the medical profession."

"Section 5. All questions of ethics in other respects shall, as far as applicable, be adjudged in accordance with the Code of Ethics promulgated by the American Medical Association, and adopted by the Academy."

In opposition to Dr. Barker's circular the following was issued by the Council of the Organization for Upholding the National Code of Ethics: "The Council of the Organization for Upholding the National Code of Ethics in the State of New York begs to call your attention to a circular recently issued, in which are proposed certain amendments to the Constitution and By-laws of the New York Academy of Medicine. The Council cannot but regret the issuing of this circular as a covert movement, under a plea for harmony, in behalf of the organized effort in opposition to the National Code of Ethics. The proposed amendments, were they adopted, would eliminate from the Constitution and By-laws everything relating to ethics, and surrender the Academy to those who advocate the abolition of all ethical codes. The Academy would thereby be deprived of the right of representation in the American Medical Association, and of affiliation with other medical organizations out of the State of New York. It may be assumed that there is no disposition on the part of those who are for upholding the National Code of Ethics to raise any discussion respecting the Code in the Academy. The Code has never been made a subject of discussion in the Academy by any one in favor of upholding it, and there is no ground for the supposition that it ever will be unless it becomes necessary in the way of defense. The resolutions presented and adopted at the last meeting of the Academy had for their object the prevention of any future discussion relating to the Code. Every true friend of the Academy is earnestly requested to attend its meetings in order to resist the introduction of discussions and controversies in relation to ethics by simply maintaining in their integrity the time-honored Constitution and By-laws of this institution, to which it owes its origin and prosperity." Signed, Abram Du Bois, Austin Flint, Austin Flint, Jr., J. W. S. Gouley, John H. Hinton, Samuel T. Hubbard, William T. Lusk, Samuel S. Purple, and T. Gaillard Thomas, *Council*.

There was an immense attendance at the meeting of the Academy, in regard to which two notices had been issued. The first announced that the proposed amendments would be moved by Drs. T. Gaillard Thomas and William Detmold; but both these gentlemen, whose names had been used without proper authorization, having declined to serve in this capacity, an "amended notice" became necessary. This gave the names of Dr. Edward L. Keyes as mover, and Dr. A. L. Loomis as seconder, of the amendments. After the reading of the minutes, the secretary read the following communication for the Council of the Academy:—

NEW YORK ACADEMY OF MEDICINE, }
No. 12 West Thirty-first Street, }
NEW YORK, October 4, 1883.

At a special meeting of the Council of the New York Academy of Medicine, held Monday evening, October 1st, 1883, it was

Resolved, That the Council advise, in the interests of the Academy and of peace and harmony, that the proposed amendments be withdrawn.

Resolved, That the Council, after careful and mature consideration, do not approve of the proposed amendments to the Constitution and By-laws.

DR. KEYES, in accordance with the programme, moved the adoption of the amendments as a whole, and made some remarks, in the course of which he stated that he firmly believed that by their adoption the Academy could secure an easy path of escape from the difficulties which now surrounded it.

The Secretary then read the amendments, and in seconding the motion for their adoption DR. LOOMIS remarked that he would urge this course, first, on the ground of expediency; secondly, because this was not the place for discussions in regard to medical codes; and, thirdly, in order to save the Academy from degeneracy, and perhaps from destruction.

DR. AUSTIN FLINT, JR., moved that the amendments take the regular course, and after some remarks by DR. HENRY, who was called to order by the chair, on the ground that such a motion was not debatable, DR. C. C. LEE moved to amend the motion to postpone by going into committee of the whole to consider the amendments. DR. FLINT claimed that such an amendment was not permissible; but the chair having decided that it was, the motion to go into committee of the whole was put to vote and carried. The President appointed Dr. Elsworth Eliot chairman, and Dr. Wesley M. Carpenter was elected secretary of the committee.

DR. ROOSA said he hoped that the President would give some expression of his motives and ideas, and accordingly DR. BARKER made some extended remarks, very much in the strain of the circular which he had issued. In concluding he took up the proposed amendments one by one, and stated what they were designed to accomplish.

When he had finished DR. FLINT, JR., took the floor and said that before the meeting every member of the Academy knew what these amendments meant. One of them provided for the extinction of the Committee on Ethics and everything connected with it. This left the Academy without a code of ethics, and of course necessitated certain changes in the Constitution and By-laws as they now existed. This was all there was about the matter. It was not of the slightest consequence what the committee of the whole had to say on the subject; but when the amendments came up for action at the next meeting all those in favor of the old Code would vote against their adoption, and all those in favor of the new Code would vote for it. It required a three-fourths vote to adopt them, and their passage, he believed, was absolutely hopeless. Consequently, he believed that the proposal of the amendments was a fire-brand, which could only have the effect of increasing the unpleasant feeling which now existed in the Academy. The question of their adoption could not come up to-night, and he certainly did not want to discuss them any more. He hoped that no friend of the National Code would say one word about them; the only way was to come to the next meeting and vote against them. Before taking his seat Dr. Flint said that he would not have spoken at all if the President had not overruled him, and decided that the amendment to go into committee of the whole was in order.

On motion of DR. BARKER, the following resolution, which was a modification of a similar one previously presented by Dr. Elsberg, was passed:—

Resolved, That in the opinion of the committee of the whole it is advisable to adopt the amendments to the Constitution and By-laws, and that the chairman be instructed to report this to the Academy.

A motion that the committee of the whole rise, report progress, and ask leave to sit again at the next meeting of the Academy was carried, and the chairman made his report. Dr. Flint's original motion that the amendments take the regular course and lie over until the next meeting was then adopted, and the Academy adjourned.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.

W. H. TAYLOR, M. D., RECORDING SECRETARY.

OCTOBER 3, 1883. Stated meeting at the hall of the Boston Medical Library Association, President PRESBREY in the chair. Present, sixteen members. The meeting was called to order at twelve o'clock, M. Records of the last meeting were read and approved.

NEW MEMBERS.

On recommendation of the Executive Board, Medical Examiners J. P. Lynde of Athol, Christopher Seymour of Northampton, F. L. Burden of North Attleborough, O. J. Brown of North Adams, and G. P. Pratt of Cohasset were unanimously elected members of the Society.

PUBLICATION OF THE TRANSACTIONS.

On motion of Medical Examiner DRAPER, *voted*: that the Standing Committee be authorized to print and publish, at the expense of the Society, an edition not exceeding three hundred copies of the Transactions for the current year; and that the edition be distributed by the Treasurer as follows: To each regular member who has paid all his assessments to date, three copies. To each contributor to the pamphlet published, ten copies. To each associate member, one copy. To each of fifteen periodicals, one copy. The balance of the edition shall be held for sale to members at cost price; to all others at the best rates which the Treasurer can arrange.

PURCHASE AND CIRCULATION OF MEDICO-LEGAL JOURNALS AND BOOKS.

Also on motion of Medical Examiner DRAPER, *voted*: that the Treasurer be instructed to expend annually before the first day of January, until further orders, from the unappropriated funds in his hands a sum not exceeding twenty dollars for journals, books, or both, devoted to legal medicine, to be circulated among such of the regular members of the Society as have paid all their assessment dues to the date on which the book or journal leaves the office of the Treasurer; the books and journals being finally deposited as the property of the Society, with the Boston Medical Library Association. *Voted*: to allow each member the use of each journal or book so purchased for three days and to follow the most convenient method, geographically, in their circulation, the execution of the plans to be left with a committee composed of the Treasurer and Medical Examiner Draper.

Theodore M. Osborn, Esq., of Peabody, was nominated for associate membership.

Medical Examiner TAYLOR read the notes of a case of delayed putrefaction, which were discussed by Medical Examiner Draper.

The President acknowledged the receipt of the *New York Medico Legal Journal*, No. 2, and the Transactions of the Philadelphia College of Physicians, Series 3, No. 6.

Recent Literature.

A Compend of Surgery for Students and Physicians. By ORVILLE HORWITZ, B. S., M. D. Philadelphia: P. Blakiston Son & Co. 1883.

A more superficial little book can hardly be imagined. To the practitioner it is useless, for it contains but a portion of the information which every physician should have at his fingers' ends, and would never solve for him a question of doubt. For the student it is a dangerous guide, as it is wanting in the detail so necessary to a beginner. The author trusts "that it will supply a want that is supposed to exist." The only want that one can conceive to be supplied by it is that of a student who at an examination wishes the aid of a very weak-kneed pony.

The Roller Bandage. By WILLIAM BARTON HOPKINS, M. D. Philadelphia: J. B. Lippincott & Co. 1883.

Dr. Hopkins has succeeded, with the aid of numerous accurate and artistic illustrations, in giving a good and graphic idea of the more common applications of the roller bandage. Many of the plates, however, notably the last one in the book, depict bandages applied with a want of neatness which would inspire horror in the mind of a careful dresser.

The author's object has been to show the methods of adapting bandages to different parts of the body rather than their uses in fixing apparatus, and in this limited field he has met with a fair degree of success.

Transactions of the Medical Society of the State of Pennsylvania, at its Thirty-Fourth Annual Session, held at Norristown, May 9, 10, 11, 1883. Volume xv. Published by the Society. 1883.

This volume of over five hundred pages contains, in addition to the papers read at the annual meeting, the reports of the various county societies, some seventeen in number, and shows them, as well as the State Society, to be in a flourishing condition, which is also evidenced by the generally high standard of the professional work represented by the papers. Among the contributors we notice several names well known throughout the country. Many of the articles have already appeared in the Philadelphia and other journals, and this substantial volume affords a permanent way of preserving them.

Quiz Compend of Viscera: A Compend of Visceral Anatomy, especially adapted to the use of Medical Students. By SAMUEL O. L. POTTER, M. A., M. D., A. A. Surgeon, U. S. Army. Philadelphia: P. Blakiston, Son, & Co. 1883.

This, as its title implies, is an interrogative compend on the viscera. It embraces minute as well as coarse anatomy. The former strikes us as particularly unsatisfactory. There are forty-one wood cuts of little merit.

Medical and Surgical Journal.

THURSDAY, OCTOBER 4, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,

No. 4 PARK STREET, BOSTON, MASS.

PRESCRIPTION WRITING.

JUST at the commencement of the academic year a few remarks on this branch of medical study may not be out of place. The student is apt nowadays to felicitate himself that polypharmacy is a thing of the past, and he is generally impregnated with the idea (not founded altogether upon fancy) that when he has learned to understand the action of a few drugs, and to express skepticism with regard to the rest, he has fulfilled the therapeutical requirements for a scientific practitioner. He is, in fact, apt, unless of an extremely practical turn of mind, to neglect treatment altogether while threading the mazes of pathological anatomy and scientific diagnosis. Now while we have every reason to congratulate ourselves that the broader and more fundamental studies occupy the greater part of the student's time, there is, we think, danger of his going too far in neglecting altogether to acquire the technique of medical practice.

The old method of study under a single physician, with all its shortcomings, had certain advantages. Although the diagnoses made at the clinical exercises were often of the variety called "snap," the student did gain some valuable points for future use which in the more scientific study at the school and hospital must of necessity be left in the background. He learned, if he used his powers of observation and reflection, what to say to the private patient and what to say to the family, and, better yet, how to keep silence where silence is golden; he learned how to comport himself in practice towards his brother practitioners; and amongst other things he learned how to write a prescription for each indication he was likely to meet. He did this because he learned that whatever the case this is the one thing which the doctor is generally called on to do. Many a graduate of our schools when he opens his office finds his ideas on these practical subjects rather vague, and while thoroughly versed in the diagnosis of diseases he may be quite at sea when first required to render a bill, to send a patient to the asylum, or to call another physician into consultation. Indeed, he will be fortunate if some awkward technical blunder does not interfere materially with his opportunities to exercise his skill in diagnosis. Most of the technicalities of practice will be learned *with* the practice, aided, perhaps, by a not too careful study of *some* of the suggestions of such an adviser as "The Physician Himself, and what

he Should Add to his Scientific Acquirements;" but every young practitioner would find it extremely convenient to be able at the outset to write a prescription to meet any ordinary requirement.

We would by no means place this branch of medical study in the very foreground; indeed, the advantage of a scientific medical education lies in the fact that the student, instead of picking up a practical point here and there, learns to develop a systematic plan of analyzing phenomena which forms a basis for all future work, and which will enable him to place his conclusions far above the plane of shrewd guessing. Still the student must never lose sight of the fact that individual practical points will also prove useful, and that the accumulation of these points depends as much upon his own exertions as upon those of the medical faculty.

The danger of forgetting the importance of *treating* disease did not exist under the old *régime*. The pupil, brought face to face with actual practice, sharing in a certain way his teacher's responsibility, and called sometimes to take his place, was inclined by force of circumstances rather to fall into the opposite error of learning to treat without learning to diagnose. He could "write for a cathartic, an expectorant, a diaphoretic, an emmenagogue" before the end of his first year; a task which, it is to be feared, proves a stumbling block to many an aspirant for the medical honors of some of our best schools, and which furnishes every year melancholy amusement for the professor of therapeutics. This by no means shows faulty instruction in therapeutics and materia medica, for this very student knows really far more of the properties and the physiological and medicinal action of the drugs for which he cannot write than his country cousin. The misfortune rather than fault lies in the fact that the Harvard student, for example, has not yet had practically brought home to him the fact that one of the tasks he will be called on to perform in his practice, is to write prescriptions, and this not under the comparatively lenient eye of the instructor, but before the unrelenting gaze of the patient, who is to pay him for doing it, and who is trying to decide whether he has come to the right doctor.

In each of the principal clinics of Germany is published a hand-book of pocket dimensions, which contains the favorite prescriptions there in use. In the Vienna hand-book the various diseases are arranged alphabetically, so that under each disease is found first the general principles of its treatment, such as "rest in bed," "water dressings," "ice," "clearing the bowels," etc., then a list of the prescriptions which may prove useful; the prescriptions, while generally characterized by great simplicity, being all written out in full form. By the study of such a book in connection with each disease the student in Germany endeavors to supplement his peculiarly scientific course. Some such plan might not be amiss for the American student. It may be objected that he would learn to depend upon the book; but this is not an objection of much weight, for he will not care to pull out his book often at the bedside, and even if he does depend upon

in the case of my venerated friend, the "older practitioner," it is clear that his "moral and ethical duties" sanctioned the habit which had governed his practice in respect to the management of such monsters as were delivered at his hands.

WILLIAM C. WEY, M. D.

ELMIRA, N. Y., September 29, 1883.

IODOFORM IN FISSURE OF THE ANUS.

MR. EDITOR, — Following the advice of Dr. Thomas Hay (as quoted in the *JOURNAL* of August 30th last, page 211), I recently ordered some suppositories, each containing two grains of iodoform, for a lady, who has been greatly plagued by fissure of the anus for three or four years, but who has emphatically objected either to incision or forcible dilatation of the sphincter; one to be inserted morning and evening, after movement of the bowels.

I saw her upon the second day, and she expressed herself as much pleased. The sphincter was so relaxed as to permit more copious evacuation, and there was none of the usually resulting pain and burning.

I saw her again on the sixth day, when she was suffering from intense headache; and was told that on the fourth and fifth days she had been annoyed by an almost irresistible desire to sleep, and an excessively bitter taste in the mouth, which still continued, in spite of the very severe pain in the head. Upon inquiry I found that, not fully carrying out my directions, she had only used eight of the suppositories — or only sixteen grains — in the six days. But the toxic effects of iodoform were unmistakable. She is now, three days later, quite recovered, after much sleep and a gentle aperient. But I think it right to record the case, as a caution to other physicians who may employ this remedy. My patient *may* be unusually sensitive to its action; but others may be as much, or more so. And, in any case, it should be carefully watched.

Very truly yours,

ALEXANDER R. BEEKER, M. D.

BERKELEY, CALIFORNIA, September 28, 1883.

MALARIA.

MR. EDITOR, — In your issue of August 30th is a review of a recent paper by Dr. C. P. Russell, of New York, on the nature of the malarial poison, and its conditioning influences.

The views held by Dr. Russell are not new, nor are they entirely original, for eight years ago I heard almost the same ideas advanced by the late Dr. George A. Ward, of Peru. Dr. Ward's experience through the mountainous regions and on the sandy plains of Peru was great, having extended over a period of about twenty years, and the large number of malarial cases he encountered throughout the country (chiefly intermittent and bilious remittent in form) soon convinced him that heat and moisture, in conjunction with an organic pabulum, did not always evolve the malarial type. Indeed, I think he stated in the *New York Medical Record*, a short time before his death, — which took place rather suddenly from a violent malarial fever, contracted at an elevation of over seven thousand feet, in a district

almost destitute of vegetation or water, — that though he did not pretend to a knowledge of the real nature of malaria, he firmly believed that neither heat, moisture, nor organic matter played any part in its evolution.

I have seen intermittent and remittent fevers as prevalent on the dry, sandy plains and through the mountains, even up to the snow line, of Peru as I have ever seen them in Panama.

During the construction of the Oroyo railway from Lima to its present terminus, fifteen miles from the summit of the Cordilleras, a violent malarial fever broke out as soon as the ground was disturbed, which carried off several thousands of workmen. This fever raged chiefly along the rainless portions of the road, that is, the lower two thirds, where the earth is always exceedingly dry and the soil thin, though it extended to an elevation of thirteen thousand feet, or nearly to the snow level. A description of this epidemic, under the title of Oroyo Fever, was published some years ago by Medical Director Browne, of the Navy, and Dr. Ward, who was a surgeon on the road at the time.

Two years ago a detachment of troops from the Chilean army of occupation in Peru was sent up the Oroyo railway and across the Cordilleras; but no sooner had they reached the snow line than a malignant malarial fever much resembling the Oroyo appeared among them, and fairly decimated the force. At the present time the Chilean troops quartered on the dry plains are suffering heavily from various forms of malarial fevers, though one not acquainted with the peculiarities of the country would pronounce their atmospheric and telluric surroundings unqualifiedly good.

Yours truly,

A. C. HEFFENGER, M. D.,

Passed Assistant Surgeon, U. S. Navy.

Miscellaneous.

THE CLIMATE OF SANTA BARBARA AND THE NORTHERN PACIFIC COAST.

AN English writer in the *Lancet* (August 25th) thus describes the climate of Santa Barbara and some other localities of the Pacific coast: At the former place the average annual rainfall is not more than sixteen or seventeen inches, and it comes chiefly in November, December, January, and February. All through the winter months roses, geraniums, verbenas, etc., flourish and bloom in the open air and without shelter, while strawberries ripen up till December, the grape ripens freely in the open, and the orange, the lemon, the Japanese persimmon, and the olive are seen in full fruit in January. The summers are dry, but not very hot, the thermometer very rarely rising to 90° F. The average temperature for July is 68° F., and that for January 53° F., giving a difference of only 15° F. Snow never falls, and even slight frosts are rare. The nights are cool all the year through, but never very cold, the average difference between the warmest part of the day and the coolest part of the night being reckoned 12° F. The winter months average 54° F., the spring 60° F., the summer 68° F., and the autumn 63° F. In his statistics of temperature and the climate of the Riviera, Dr. H. Hassall gives in round numbers the following: Winter 55° F., spring, 50° F., summer 63° F., and autumn 72° F., the average for the year being a little over 60° F. These figures apply chiefly

to San Remo, the numbers given for Bordighera and Mentone being a little higher, and those for Nice a little lower. At the outset I alluded to the advantages of those climates that permitted the greatest number of hours to be spent in the open air. The following computation was made by a patient staying at Santa Barbara. During the year (February 1st to January 31st) there were three hundred and ten pleasant days, when an invalid might be out five or six hours with safety and comfort; ten windy days and five wet ones, when he would be kept in-doors all day; the remainder cloudy and showery days, on which he could be out part of the day with comfort. A feature of open-air life that has been largely tried, and with the best results, at Santa Barbara, is camping out. Patients living there get into the habit of being so much out of doors that the transition to camp life is easy, and has been by some carried on for four or five months continuously. In California horses are plentiful, and everybody rides. The "vaquero" spends his life in the saddle. Mere children are seen mounted on a good-sized mustang, which they manage with the ease of perfect horsemanship. Visitors buy or hire horses for the season, and the invalid, too, enjoys his morning ride. As the place has grown, so pleasant society has increased, while good shops, a club, and good hotels have rapidly sprung up.

Los Angeles, which I have already mentioned, lies a little off the coast, about a hundred miles southeast, and has a climate rather warmer and drier than Santa Barbara. It is a town of considerable size, and is the centre of a large orange-growing and wine-making district. A hundred and twenty miles further south lies San Diego, with an annual mean temperature of 62° F., and a rainfall rather under eleven inches. Going northwards from Santa Barbara we have Monterey, a favorite resort with the people of San Francisco, from which it is distant a little over a hundred miles, and is prettily situated on a bay opposite to Santa Cruz. At certain seasons San Francisco is much exposed to cold winds off the sea, and to escape these people betake themselves to Monterey, with its cedars and cypresses, and its sheltered situation. In December the climate of San Francisco was delightful, far more pleasant than in September, being moderately warm and equable. In summer the early part of the day was often very hot, but towards noon a cold wind would sweep inwards off the sea with chilling and penetrating force. Passing to the northward of San Francisco we have, in Western Oregon and in Washington Territory, a lower temperature and a long wet winter, with a rainfall of as much as forty-five inches or more. This district lies to the west of the Cascade range of mountains, and extends as far north as Puget Sound. Immediately to the north of this are the Straits of San Juan de Fuca, separating British from American territory. On the northern shores of the straits, at the southeast corner of Vancouver Island, the town of Victoria, capital of British Columbia, is picturesquely situated.

It is surprising, at first sight at least, to find, nearly a thousand miles north of San Francisco, a climate closely resembling that of the English south coast, having a winter average temperature of 42° F., and a summer of a little over 60° F. This mildness, which extends more than three hundred miles north of Victoria, is attributed to a warm stream called the Japanese current, which strikes the Queen Charlotte Islands and flows southerly along the shores of Vancouver

Island. Victoria bids fair to become a favorite winter residence and sanitarium on account of the beauty of its surroundings and the equability of the climate.

THE SURGERY OF THE LUNGS.

THE *Medical Times and Gazette* reproduces a paper by Dr. Bull, of Christiania, communicated to the *Nordiskt Medicinskt Archiv*, containing a case bearing on the question of operative proceedings in diseases of the lungs. The author also gives a brief review of the literature relating to the operations hitherto performed in diseases of the lungs, together with some observations on the indications connected with the opening of tuberculous cavities, and he draws attention to some new possibilities of limited expiratory expansion of the pectoral wall. The case was that of a man, twenty-nine years old, who entered the State Hospital of Christiania, exhibiting all the signs of advanced pulmonary tuberculosis, such as hectic fever, violent cough, abundant muco-purulent expectoration, emaciation, and anæmia. In the first, and partly in the second, left intercostal space, external to the left sternal border, there was observed during the fits of coughing a considerable and clearly limited expansion of the pectoral coverings, which circumstance was not observed in tranquil breathing. This limited expiratory expansion was thought to be due to a superficial cavity adherent to the thorax and, perhaps, ulcerated by the pleural adhesion. Viewing the possibility of the suspected cavity offering an advanced process of ulceration; and of the secretion, incompletely expectorated, flowing into the neighboring bronchi; considering that the fever and the cough were partly relieved by the opening of the cavity externally by means of drainage and disinfection, and that the expiratory expansion in front might perhaps indicate a commencing perforation of the thoracic wall; taking all these matters into consideration it was determined, with the consent of the patient, to try the operation. This was accordingly performed, and after the perforation of the thoracic wall the finger could be introduced into a small empty cavity, limited on all sides by smooth walls, the base of which was formed by a solid elastic tissue. There was no sound of air entering or going out. The day after the operation, during a fit of coughing, there was a sudden discharge by the wound of a liquid like that of expectoration, and this discharge continued abundant, but without relief to the patient, who died in six days.

On post-mortem examination the left lung was found to be separated almost entirely by from three to four centimetres from the thoracic wall, and there were only a few filiform adhesions with the upper parts. There was fibrinous pleurisy and a little pus in the pleural cavity. At the apex of the lung there was a large superficial cavity. In other respects in both the lungs there were the usual indications of phthisis. The differential diagnosis between a cavity and a pneumothorax in cases such as the above cannot be made with certainty, and, in view of the possibility of mistake, Dr. Bull advises that pulmonary operations should always be performed with the aid of antiseptics, so that if the incision reveals a pneumothorax the wound may then be closed and the operation be regarded only as "diagnostic." Dr. Bull has found in medical literature the records of nineteen cases in which the opening of

pulmonary cavities has been undertaken. Five of these, however, are imperfectly reported, or the diagnosis was too doubtful to be of any service. Of the rest of the cases, two were instances of bronchiectatic cavities, in one case the bronchiectatic cavity was consecutive to pneumonia, five were cases of pulmonary abscess, three of pulmonary gangrene, two of tuberculosis, and one of echinococcus of the lung. The results of the operations were as follows, namely: Cases perfectly cured, two; very marked improvement, two; more or less relief, seven; no ill consequences, one; cases made worse, two. As to the tuberculous cavities, experience is almost entirely wanting as to the effect of artificial pulmonary fistulae, and it belongs to the future to demonstrate whether an operation of this kind is more dangerous in phthisical patients; but even when this proceeding might appear to be without danger, it should not be performed at a too advanced period of the disease.

PARTURITION AMONG THE MAORIES.

IN connection with the articles that have appeared in various periodicals within the past year or two regarding labor among primitive and barbarous peoples, we make the following extracts from a letter in the *Australasian Medical Gazette* (May, 1883), from a practitioner who has had abundant opportunity to witness the customs in that regard among the Maories. The women are as a rule very well formed, and in ordinary labors they manage things admirably, only calling in a white doctor when there is great delay, or when from other causes they become frightened. The writer says:—

The Maori *modus operandi* during labor is as follows: When the woman is taken in labor, she, with one or two of the same sex, goes into the titree, or manuka scrub, some two hundred yards or so from the whare, and if the weather is bad a tent is erected, according to the circumstances of the family. In fine weather no preparation is made. They are never confined in their own whares. The posture during labor is the kneeling one; the woman clasping her arms around one of the attendants, who supports and presses the abdomen, while the other receives the child at birth from behind.

The placenta is removed by pressure on the womb through the abdominal wall, and if there is any difficulty, the woman goes at once into the cold or tepid water, and by kneading the womb, as above described, the object is attained.

The placenta is invariably buried secretly. Allowing time and using pressure from without are their only modes of conducting labors. In cases that did not yield to these means the woman was allowed to die.

They know no internal operations at all; but as one of my most intelligent Maori informers said, "There is very seldom any trouble. Often the woman delivers herself alone, and brings in a kit of potatoes as well as the child."

On the completion of labor the mother and child bathe in the nearest cold water lake or creek (this is a custom which may some day be employed in our midwifery system for expelling clots), and after a good washing return to the whare. In very cold weather tepid water is used to wash the infant. In this district

warm water is used often for washing the first-born, but should the child die, cold water is always used for succeeding children in that family. This is a Maori custom.

In delayed labors the Maori priest-doctor, or "tohunga," is called in. He with incantations, etc., beguiles the weary hours, and should time effect the desired object, he is accounted a great man.

In connection with their free use of cold baths, the author mentions the fact, interesting to compare with our own practice of hydrotherapy, that having among the Maories a large number of fever cases (badly marked typhoid, with symptoms of an aguish type) he found it was the custom of his patients to bathe regularly in the cold water creek flowing through the "pah," or in the lake, whenever they felt their "skins very hot." No ill effects followed, and almost all the cases did well.

THE SENSE OF DIZZINESS IN DEAF-MUTES.

THE *Practitioner*, August, 1883, refers to experiments by Dr. James, of Cambridge, quoted in the *Otological Journal* for October, 1882, with a view to discover how far the directing power attributed to the semicircular canals is defective in persons whose organs are presumably damaged, namely, the inmates of deaf-mute institutions. His theory is that seeing the consciousness of movement of the head through space when exaggerated causes vertigo, as in whirling around rapidly, rising from the stooping posture suddenly, etc., "disease of the internal ear is likely to confer immunity from dizziness." He does not give any classification of the persons experimented on as to the lesions causing the deafness, which, indeed, it is not perhaps possible to do very precisely according to our present powers of diagnosis, and he has classed congenital deaf-mutes with those in which the deafness came on at various ages through disease, not having apparently found any difference in the results in the two classes. He has, however, eliminated, so far as possible, all causes of vertigo except that arising from the "directing sense." He has kept the patients' eyes closed so that they should not be confused by visual images on the retina in whirling around, and in almost all the experiments has used passive rotation so as to get rid of any muscular unsteadiness. His results are certainly very remarkable. He first tested 200 students and tutors in the Harvard College, and found only one among them free from dizziness on rotation, whereas of the deaf-mute cases, 519 in number, 186 remained perfectly free from the feeling, and 134 others are stated to have been only slightly affected. Passive rotation was effected by placing the patient in a swing of which the two ropes were tightly twisted, and then allowed to untwist. The swing was stopped when it had nearly come to rest, and the patient directed to walk to a fixed point, the dizziness being judged of by the irregularity of his gait.

Further inquiry was made among the "non-dizzy cases" as to whether the feeling was experienced in sudden rising from the stooping posture or other movements than whirling. The replies varied, and so were unsatisfactory.

Again, assuming that sea-sickness arises through over-excitement of the directing sense, as maintained by Helmholtz in his *Optics*, written before this special function of the semicircular canals was discovered, in-

quiry was made as to whether any of the deaf-mutes had suffered in rough weather at sea. Of fifteen cases who had been at sea not one had been affected. This result, though only negative evidence, is confirmatory of the theory, and he bases thereon a noteworthy suggestion of counter-irritation of the semicircular canals by blisters behind the ears as a remedy in that distressing ailment.

The noteworthy remark is made that the ataxia of the deaf is chiefly found in those who have become deaf from meningial or other disease, and is rare in congenital cases. This is accounted for by supposing that in the latter cases the central directing power has never formed any connection with the canals, whereas in the former such connection formed in early life, and lost through disease, left the central organ at fault. Again, it is suggested that as the ataxia tends to improve with time, no doubt from the formation in most instances of new peripheral connections, it may in some cases, as after diphtheria, be due to a temporary anæsthesia of the canal.

The investigation, though unfinished and in many respects inconclusive, is very suggestive and interesting, as it brings clinical facts in relation with recent physiological discoveries.

THE SIGNIFICANCE OF APPEARANCES OF THE TONGUE.

A COURSE of lectures on diseases of the tongue, delivered by Prof. Jonathan Hutchinson before the Royal College of Surgeons of England, is now appearing in the *Medical Press and Circular*. At the conclusion of the introductory lecture we find some suggestions of a practical nature regarding the interpretation of tongue symptoms, which we quote:—

First, we must avoid assuming hastily that the condition present has any connection with the disorder for which the patient consults us. Many patients have habitually a profuse growth of filiform papillæ and great tendency to the accumulation of fur. In others the papillæ are curiously absent, and the tongue may look bald or rough. In others the furrows may be well marked, and the peculiar fern-leaf pattern present, and yet these several conditions may imply nothing whatever as regards the patient's health.

In all conditions of peculiarity it is well to inquire whether the patient has ever at any former time been salivated or suffered from sore mouth. For it may easily be the fact that some attack of stomatitis, long past, may have left the tongue flabby, indented at its edges, fluted on its surface, or more or less bald.

In cases in which we have satisfied ourselves that the conditions shown are neither personal peculiarities nor yet the consequences of previous disease, we ought next to inquire carefully whether any local conditions are present in the mouth which will explain them, and by no means jump to the conclusion that they denote disorder of the stomach or liver. If the tongue is dry we inquire whether the nostrils are stopped, and if it is sore we must examine the teeth and ascertain whether from sharp, broken points, from stopping with amalgam, or accumulation of tartar, any possible source of irritation exists.

If we have failed to discover in the mouth any cause for disease on the surface of the tongue we must still hesitate as to suspicion of visceral or blood disorder, and ask whether it be not possible that some

irritant may have been introduced in the way of food. There are many fallacies in this direction.

Lastly, if we feel able to confidently exclude all local causes, and obliged to believe that the state of the tongue is in direct connection with the state of the bodily health, we have still before us the difficult task of deciding as to what the nature of the bond of connection may be.

The state in question may still possibly be in no way symptomatic of other disorder, and not in any degree consequent on it, but rather part of the general disease.

Above all we must be on our guard against believing that the state of the tongue is a trustworthy criterion as to that of the mucous membrane of the stomach, and remember that for the most part a furred tongue implies that no food has been eaten and little more, whilst glossitis and gastritis are conditions which are mutually independent, and but seldom coexist.

THE COUVREUSE, OR MECHANICAL NURSE.

We quote from the *Lancet* (August 11th) the following more detailed description of what was noticed in the *JOURNAL* some months ago:—

It was in 1878 that Dr. Tarnier, when visiting the apparatus devised by M. Odile Martin for artificially hatching and rearing chickens at the Jardin d'Acclimatation, suggested that a similar method might be applied with advantage to infants, especially in cases of premature birth. Two years elapsed, however, before any attempt was made to carry out this proposal; but in the course of the year 1880 a *couvreuse* was made, and brought to the hospital of the Maternité. This is a plain wooden case or box, measuring about two feet eight inches by two feet four inches, and two feet four inches in height. The box has a double covering, the space between being filled with sawdust to retain the heat, and is divided into two parts. The lower half contains a reservoir, which holds about sixty litres of water, and is fed by a patent boiler that stands outside the box, and is warmed by an oil lamp; or hot water may be used without recourse to the lamp. The upper portion of the box forms a warm chamber, where a little basket or cradle is placed, large enough to hold two infants. From an opening at the side, this cradle may be withdrawn, while the top of the box has a double glass covering, so that the children and the thermometer lying by their side can be constantly watched. If the water used in the first instance is cold, it takes a long time to attain the required temperature; but once this is done the lamp need only be relit three or four times during the course of the day. It is best to warm the apparatus while the infants are being fed or washed. The temperature within the *couvreuse* is generally maintained at 86° F., and though the contrast on withdrawing the child to be fed or washed is very great, amounting often to 30° F., colds are not so frequent as among the infants nursed in the ordinary manner. Altogether the experiment is considered so successful, that it is proposed to supply all the hospitals of France with a *couvreuse*, and there is every reason to anticipate good results from this measure. Nor is this all. A small portable *couvreuse* is now about to be tried which could be carried by hand from house to house. After this we shall probably have perambulators constructed on the same model. In conclusion, we should remark that, though no very careful experiments have been

made with respect to the ventilation within the *couvreuse*, yet this is evidently sufficient. Apertures are made in the lower portion of the box, the fresh air travels over the hot water reservoir, and is thus warmed before it reaches the child. The very great difference of temperature within the *couvreuse* insures a constant current of air, though the child is protected by its cradle and clothes from any draught.

CATALEPTIC STATE OF THE MUSCLES.

THE *Glasgow Medical Journal* has a note from the *Gazette des Hôpitaux* (March 20, 1883) on the following phenomenon stated by M. Brown-Séquard at the Société de Biologie. He remarked that a condition resembling catalepsy may be produced in the muscles, and in them only. It cannot well be caused by the nervous system since this phenomenon may be produced more than two hours after death, and since the destruction of the spinal cord does not modify, but rather increases, it. This cataleptic state is so clear as to be beyond doubt. Any part will keep the position in which it is placed, and is always rigid; this is not cadaveric rigidity since it does not pass off. It is possible for this to occur in man.

It is known that convulsive movements have been observed in death from cholera and yellow fever. M. Brown-Séquard cited an example coming under his own notice. A man, several hours after death from cholera, brought his two hands together, lifting his arms into the air, and continued to repeat this for some time in the clearest way possible. An English author has recorded the same facts following a death from yellow fever. Lastly, convulsive movements are sometimes observed in a recently amputated limb.

M. Brown-Séquard has no doubt that these phenomena have their seat in the periphery, and not in the nervous centres. In summing up these facts we arrive at the conclusion that a peculiar state of the muscles, analogous to catalepsy, may occur, and that the contractile tissues may have certain actions more or less similar to those produced by the influence of the nervous system. The contractile tissues are, therefore, more closely allied to the nervous system than is generally supposed.

JAMES A. FLEMING, M. D.

ON the last day of September, at the Massachusetts General Hospital, died Dr. James A. Fleming, a physician who, though but thirty-one years of age, and but a comparatively few years in practice, had already won hosts of friends, and established what bade fair to be a very lucrative business.

It is rare to find a youth who encounters as successfully as Dr. Fleming so many obstacles in the way of advancement on his chosen path in life, and who exhibits a steady intellectual and professional growth in the face of poverty and encouragement half-hearted or wholly wanting.

Dr. Fleming from almost early childhood was obliged to rely on his own endeavors for support, and occupied many positions which would not be thought desirable by the average student, but which were all honorable in so far as they enabled him to earn an honest livelihood and to pursue his studies. He received the best education afforded by the Boston public schools, entering the Mayhew, going thence to the

English High, where he graduated at the head of his class with the respect and esteem of his teachers. A little later he entered the Harvard Medical School, from which he graduated with credit, taking his degree after eighteen months' service at the City Hospital as interne. In the competitive examination for this position he is said to have passed the best examination of all the applicants.

After leaving the Hospital he opened an office at the North End, and, with the exception of a short European tour, he steadily devoted himself to the practice of his profession in that quarter of the city. He rapidly won the confidence of many of the best families there, and at the time of his death had the brightest prospects for a large and lucrative practice.

He was a constant student, having already acquired a good knowledge of the French and Italian languages, and becoming convinced that to keep abreast of the times he needed also to be able to read the latest medical literature of Germany, he devoted himself with unusual zeal and perseverance to the acquirement of German, in which he made rapid progress. Dr. Fleming was for several years a member of the School Board, being at the time of his death chairman of the Committee on Accounts, and enjoying the confidence and respect of his associates. He was also surgeon of the Ninth Regiment M. V. M., at the last encampment of which began the illness which resulted in his death. His ready wit, geniality, and other social qualities endeared him to a circle of friends, many of whom were of different race, creed, and profession. As secretary of one of the social clubs of medical men of the city he contributed in no small degree to the enjoyment of the members, by whom he will be sadly missed.

Dr. Fleming's illness was of comparatively short duration, and its nature somewhat obscure, though pointing toward typhoid fever. He was not only supposed to be in no danger by his friends and medical attendants, but was thought to be just "comfortably sick." He, on the other hand, was thoroughly and firmly convinced that he should never recover, and he made every preparation, even to the smallest matters, for the event of his death.

The kindness and consideration for the poor which he ever manifested in his practice was strikingly illustrated in his very last moments, when, thoroughly conscious of his rapidly approaching dissolution, he said to his friend, Mr. Dacy, "I'd like the staff of the regiment to come to my funeral, but don't have the regiment turn out, for the men are poor, and cannot afford to lose a day's work."

In his death the medical profession have lost from their ranks a young man of excellent promise, a careful and conscientious physician, an earnest student, and an honorable gentleman, who would have reflected credit upon his profession and his city had he been spared.

At his funeral, which was very largely attended, were present very many of his medical brethren.

—The *Medical Press* (September 5th) contains the report of a case of hydrophobia occurring four hundred and fifty days after the bite which caused it. The animal showed marked signs of rabies at the time, but the wound had been thoroughly cauterized with a hot iron.

REPORTED MORTALITY FOR THE WEEK ENDING SEPTEMBER 29, 1883.

Twenty-three Massachusetts towns.	182,027	55	19	20.00	16.36	16.36	1.82	1.82

Deaths reported 3667: under five years of age, 1142: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 673, diarrhoeal diseases 281, consumption 275, lung diseases 189, diphtheria and croup 141, typhoid fever 84, malarial fevers 63, scarlet fever 50, whooping-cough 19, small-pox 13, cerebro-spinal meningitis nine, erysipelas seven, measles three, puerperal fever three. From *malarial fevers*, St. Louis 16, New Orleans 15, New York 12, Brooklyn eight, Baltimore seven, Philadelphia and Salem two each, Fall River one. From *scarlet fever*, Philadelphia and Chicago 11 each, St. Louis eight, New York five, Brooklyn and Baltimore four each, Pittsburg three, Boston, New Orleans, Buffalo, and Charleston one each. From *whooping-cough*, District of Columbia six, New York five, Brooklyn four, Chicago three, Buffalo one. From *small-pox*, New Orleans 10, Philadelphia two, Nashville one. From *cerebro-spinal meningitis*, New York two, Chicago, Boston, Baltimore, Cincinnati, Milwaukee, Lowell, and Salem one each. From *erysipelas*, Boston two, Brooklyn, Chicago, Baltimore, Cincinnati, and District of Columbia one each. From *measles*, Baltimore, District of Columbia, and New York one each. From *puerperal fever*, Chicago, Providence, and New Haven one each.

Two cases of small-pox were reported in St. Louis; typhoid fever 55, diphtheria 31, and scarlet fever 28 in Boston.

In 42 cities and towns of Massachusetts, with an estimated population of 1,165,386 (estimated population of the State 1,922,530), the total death-rate for the week was 20.08 against 17.62 and 22.45 for the previous two weeks.

In the 28 greater towns of England and Wales, with an esti-

mated population of 8,620,975, for the week ending September 15th, the death-rate was 19.3. Deaths reported 3184: diarrhoea 314, acute diseases of the respiratory organs (London) 157, scarlet fever 111, fever 72, whooping-cough 57, measles 52, diphtheria 28, small-pox (Birmingham nine, Sunderland three, London one) 13. The death-rates ranged from 13.2 in Bradford to 26.9 in Manchester; Bristol 14; London 16.6; Nottingham 17; Leicester 18.9; Birkenhead 20.6; Birmingham 21.3; Brighton 22.5; Leeds 24.3; Liverpool 24.7; Blackburn 25. In Edinburgh 13.7; Glasgow 24.6; Dublin 27.5.

For the week ending September 8th, in 170 German cities and towns, with an estimated population of 8,716,123, the death-rate was 25.4. Deaths reported 4112; under five years of age, 2358; consumption 458, diarrhoeal diseases 384, lung diseases 252, diphtheria and croup 183, scarlet fever 87, typhoid fever 68, whooping-cough 50, measles and röteln 34, puerperal fever 22. The death-rates ranged from 10.7 in Metz to 35.3 in Magdeburg; Königsberg 32.2; Breslau 31.8; Munich 28; Dresden 27.4; Berlin 27.7; Leipzig 17.8; Hamburg 22.5; Cologne 23.4; Frankfurt 14.9; Strasburg 20.1.

For the week ending September 15th, in the Swiss towns, there were 37 deaths from diarrhoeal diseases, consumption 28, lung diseases five, measles two, scarlet fever two, diphtheria and croup two, typhoid fever one, puerperal fever one. The death-rates were, at Geneva 11.3, Zurich 14, Basle 19.8; Berne 23.7.

The meteorological record for the week ending September 29th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

Date.	Barom-eter.	Thermom-eter.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM SEPTEMBER 22, 1883, TO OCTOBER 2, 1883.

RICHARD, CHARLES, first lieutenant and assistant surgeon. Granted leave of absence for two months, with permission to apply for extension of two months. Paragraph 1, S. O. 49, Military Division of the Atlantic, September 25, 1883.

WAKEMAN, WILLIAM J., first lieutenant and assistant surgeon. Relieved from temporary duty at Fort Sidney, Neb., to rejoin his proper station at Fort D. A. Russell, Wyoming. Paragraph 5, S. O. 103, Department of the Platte, September 22, 1883.

TILTON, H. R., major and surgeon. Assigned to duty as post surgeon at Fort Wayne, Michigan. Paragraph 4, S. O. 183, Department of the East, September 28, 1883.

BRECHEMIN, LOUIS, captain and assistant surgeon. Relieved from duty at Fort Columbus, New York Harbor, and assigned to duty at Fort Wadsworth, New York. Paragraph 5, S. O. 183, Department of the East, September 28, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING WEEKS ENDING SEPTEMBER 29 AND OCTOBER 6, 1883.

BEARDSLEY, G. S., surgeon, granted leave of absence for six months, with permission to leave the United States.

AUSTIN, A. A., passed assistant surgeon, orders to Naval Hospital, New York, revoked, and placed on waiting orders.

LIPPINCOTT, GEORGE C., passed assistant surgeon, ordered to the Naval Hospital, New York.

PECK, GEORGE, medical director, detached from the Naval Hospital, Mare Island, Cal., and placed on waiting orders.

McMURTRIE, D., surgeon, and CRAWFORD, M. H., passed assistant surgeon, ordered to report at Washington, D. C., October 3d, for medical survey.

Du Bois, F. L., surgeon, detached from Naval Rendezvous, Philadelphia, and ordered as member of the Medical Examining Board, Philadelphia.

RUSH, CHARLES W., passed assistant surgeon, detached from the Naval Hospital, New York, and ordered to the Receiving Ship Colorado, New York.

JONES, M. D., passed assistant surgeon, detached from the Naval Hospital, Washington, D. C., and ordered to the Naval Hospital, New York.

ASHBRIDGE, RICHARD, passed assistant surgeon, detached from the Naval Academy, and ordered to the U. S. S. Swatara.

THE SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY will meet on Saturday, October 13, 1883, at 7.45 o'clock, at 19 Boylston Place. Paper: Nineteen Cases of Internal Urethrotomy, with Remarks, Dr. F. S. Watson. Dr. G. H. Tilden will open the discussion.

H. C. HAVEN, Secretary.

BOOKS AND PAMPHLETS RECEIVED.—Elements of Histology. By E. Klein, M. D., F. R. S. Illustrated with One Hundred and Eighty-One Engravings. Philadelphia: Henry C. Lea's Son & Co. 1883.

Transactions of the Michigan State Medical Society for the Year 1883. Lansing. 1883.

Eclectic Medical College of the City of New York. Twenty-Third Announcement and Catalogue. 1883.

Transactions of the Medical Society of the State of Pennsylvania at its Thirty-Fourth Annual Session. Held at Norristown, May 9-11, 1883. Volume XV. Published by the Society. 1883.

Remarks on Hydrophobia. Read before the Philadelphia County Medical Society, May, 1883. By Charles W. Dulles, M. D. (Reprint.)

Types of Insanity. An Illustrated Guide in the Physical Diagnosis of Mental Disease. By Allan McLane Hamilton, M. D. New York: William Wood & Co. 1883.

Cases of I. Rudimentary Uterus and Vagina. II. Cyst of Gartner's Canal. A Paper Read before the Maine Medical Association, June 12, 1883. By Stanley P. Warren, M. D., of Portland. 1883.

The Influence of Medical Men. By Nathan Allen, M. D., of Lowell, Mass. Read before the American Academy of Medicine at its annual meeting in Philadelphia, October 26, 1882.

A Complete Handbook of Treatment. Arranged as an Alphabetical Index of Diseases to facilitate Reference, and containing nearly One Thousand Formulas. By William Aitken, M. D. (Edin.), F. R. S. New York: Bermingham & Co. 1882.

The Pathology, Diagnosis, and Treatment of the Diseases of Women. By Graily Hewitt, M. D. Lond., F. R. C. P. A New American from the Fourth Revised and Enlarged London Edition. With Two Hundred and Thirty-Six Illustrations. Edited, with Notes and Additions, by Harry Marion-Sims, M. D. Two volumes. New York: Bermingham & Co. 1883.

A Practical Manual of the Diseases of Children, with a Formulary. By Edward Ellis, M. D. Fourth Edition, Revised and Enlarged. New York: Bermingham & Co. 1882.

An Encyclopædic Index of Medicine and Surgery. Edited by Edward J. Bermingham, A. M., M. D. New York: Bermingham & Co. 1882.

Insanity, its Classification, Diagnosis, and Treatment. A Manual for Students and Practitioners of Medicine. By E. C. Spitzka, M. D. New York: Bermingham & Co. 1883.

The Diagnosis and Treatment of Diseases of the Ear. By Oren D. Pomeroy, M. D. With One Hundred Illustrations. New York: Bermingham & Co. 1883.

Practical Clinical Lessons on Syphilis and the Genito-Urinary Diseases. By Fessenden N. Otis, M. D. New York: Bermingham & Co. 1883.

A Pocket Book of Physical Diagnosis of the Diseases of the Heart and Lungs for the Student and Physician. By Dr. Edward T. Bruen. Second Edition, Revised, with Additional Illustrations. Philadelphia: P. Blakiston, Son & Co. 1883.

The Roller Bandage. By William Barton Hopkins, M. D. With Seventy-Three Illustrations. Philadelphia: J. B. Lippincott & Co. 1883.

Quiz-Compends No. 9. A Compend of Surgery for Students and Physicians. By Orville Horwitz, B. S., M. D. With Fifty Illustrations. Philadelphia: P. Blakiston, Son & Co. 1883.

THE NEW CENTURY AND THE NEW BUILDING OF THE MEDICAL SCHOOL OF HARVARD UNIVERSITY.

BY OLIVER WENDELL HOLMES, M. D., LL. D.

THE Medical School of Harvard University enters, with the commencement of the present season, upon the second century of its existence. By a fortunate coincidence it takes possession at this same time of the noble edifice which a generous public has reared for the use of the teachers and students of this institution.

Yesterday; to-day; to-morrow. Let us look backward at the period when this school began its teachings, and mark some of the longer strides which bring the professional condition of the earlier epoch to that of our own. Let us see where we stand to-day, and we shall know better what to hope for the future of the teaching, the science, and the art of healing.

We are in the habit of counting a generation as completed in thirty years, but two lives cover a whole century by an easy act of memory. I, who am now addressing you, distinctly remember the Boston practitioner who walked among the dead after the battle of Bunker's Hill, and pointed out the body of Joseph Warren among the heaps of slain. Look forward a little while from that time to the period at which this Medical School was founded. Eight years had passed since John Jeffries was treading the bloody turf on yonder hill-side. The independence of the United States had just been recognized by Great Britain. The lessons of the war were fresh in the minds of those who had served as military surgeons. They knew what anatomical knowledge means to the man called upon to deal with every form of injury to every organ of the body. They knew what fever and dysentery are in the camp, and what skill is needed by those who have to treat the diseases often more fatal than the conflicts of the battle-field. They knew also, and too well, how imperfectly taught were most of those to whom the health of the whole community was intrusted.

Dr. John Warren, a younger brother of Dr. Joseph Warren who fell at Bunker's Hill, was the first mover in the project of founding a medical school in connection with Harvard College, and was the first Professor of Anatomy and Surgery. Those who remembered his teaching have spoken to me with admiration of the eloquence and enthusiasm with which he lectured. Dr. John Warren was a man of great energy, spirit, and ability. The Lectures of the newly founded school were delivered in Cambridge until the erection of the building known as the Massachusetts Medical College, in Mason Street, in the year 1815. It was no easy matter for a busy Boston practitioner to deliver a course of lectures in the University town. But Dr. Warren did not ask whether it was easy or not. "In the fulness of professional business he daily passed over Charlestown ferry to Cambridge, there not being a bridge at that time; and sometimes, when impeded by ice, was compelled to take the route through Roxbury and Brookline to Cambridge, and to return on the same morning, after himself performing the dissections and giving a lecture sometimes three hours long." So tells us worthy Dr. Thacher, in the Appendix to his American Medical Biography.

Benjamin Waterhouse, honorably known for having been the introducer of vaccination into America, was the first Professor of the Theory and Practice of Medicine. I remember him well, and carry the scar of the vaccination he performed on me. His powdered hair and queue, his gold-headed cane, his magisterial air and diction, were familiar to me from my boyhood. Dr. Waterhouse had his degree from Leyden, where he wrote and defended a Thesis, *De Sympathia Partium Corporis Humani, ejusque in explicandis et curandis morbis necessaria consideratione*. He had some learning, which he was disposed to make the most of, as perhaps we all are if we have it, and laid himself open to the playful sallies of the students of his time, one of whom announced a course of Lectures on Oudenology, which was supposed to be a travesty of some of his prelections.

The first Professor of Chemistry was Aaron Dexter. It was the forming period of that science. Black, Cavendish, Priestley, Lavoisier were building it up with their discoveries. A course of Chemical Lectures delivered in Boston or Cambridge at that day was probably, as it certainly was at a later day, very entertaining and not wholly uninteresting. Phlogiston had not yet definitively taken itself to the limbo of negative entities. But however crude the theories, we may be pretty sure that there was left in the student's mind a memory of startling precipitations, of pleasing changes of color, of brilliant coruscations, of alarming explosions, and above all of odors innumerable and indescribable.

It is sad to think that Professors honored in their day and generation should often be preserved only by such poor accidents as a Sophomore's jest or a graduate's anecdote. The apparatus of illustration was doubtless very imperfect in Dr. Dexter's time, compared to what is seen in all the laboratories of to-day. We may admire his philosophy and equanimity, therefore, in recalling the story I used to hear about him.

"This experiment, gentlemen," he is represented as saying, "is one of remarkable brilliancy. As I touch the powder you see before me with a drop of this fluid, it bursts into a sudden and brilliant flame," which it most emphatically does *not* do as he makes the contact. "Gentlemen," he says with a serene smile, "the experiment has failed,—but the principle, gentlemen, the principle remains firm as the everlasting hills."

Three teachers only, where we have forty, or nearly that number! But when the great University of Göttingen was established the illustrious Haller filled the one Chair of Botany, Anatomy, Surgery, and Medicine. I called it a Chair,—it was rather a Settee of Professorships.

It is to be regretted that we have not a list of the text-books in use during that first period of the School. Dr. Waterhouse would naturally refer his students to the learned Gaubius, the voluminous Van Swieten, the illustrious Boerhaave. The excellent Dr. Fothergill was his uncle; the immortal Jenner was his second Creator, and their names, with that of Dr. Lettsom, were often on his lips. Sydenham, Pringle, and Cullen he speaks of as being in the hands of all his students, and his references show a considerable extent of reading.

The text-books in Anatomy were probably Cheselden and Monro, perhaps Winslow, and, for those who could read French, Sabatier. The Professor himself had the magnificent illustrated works of Albinus and of Haller, the plates of Cowper (stolen from Bidloo) and others. The student may have seen from time to time

if he did not own, the figures of Eustachius and of Haller. Haller's First Lines of Physiology were doubtless in the hands of most students. The works of Pott, of Sharp, and most of all of John Hunter, were taking the place of Heister and the other earlier authorities.

Smellie was probably enough the favorite in his department. What chemical text-books Dr. Dexter put into the hands of his students in 1783 I will not venture to conjecture.

And now I will ask you to take a stride of half a century, from the year 1783 to the year 1833. Of this last date I can speak from my own recollection. In April, 1833, I had been more than two years a medical student attending the winter lectures of this school, and have therefore a vivid recollection of the Professors of that day. I will only briefly characterize them by their various merits; not so much troubling myself about what may have been their shortcomings. The shadowy procession moves almost visibly by me as I speak: John Collins Warren, a cool and skillful operator, a man of unshaken nerves, of determined purpose, of stern ambition, equipped with a fine library, but remarkable quite as much for knowledge of the world as for erudition, and keeping a steady eye on professional and social distinction, which he attained and transmitted: James Jackson, a man of serene and clear intelligence, well instructed, not over book-fed, truthful to the centre, a candid listener to all opinions; a man who forgot himself in his care for others and his love for his profession; by common consent recognized as a model of the wise and good physician: Jacob Bigelow, more learned, far more various in gifts and acquirements than any of his colleagues; shrewd, inventive, constructive, questioning, patient in forming opinions, steadfast in maintaining them; a man of infinite good nature, of ready wit, of a keen sense of humor, and a fine literary taste; one of the most accomplished of American physicians; I do not recall the name of one who could be considered his equal in all respects: Walter Channing, meant by nature for a man of letters, like his brothers William Ellery and Edward; vivacious, full of anecdote, ready to make trial of new remedies, with the open and receptive intelligence belonging to his name as a birthright; esteemed in his specialty by those who called on him in emergencies. The Professor of Chemistry of that day was pleasant in the lecture room, rather nervous and excitable, I should say, and judiciously self-conservative, when an explosion was a part of the programme.

Those who are curious to know what hand-books we students used in 1833 will find they were nearly as follows. In Anatomy, the works of John and Charles Bell, that of Wistar, and the Dublin Dissector. In Physiology, Haller's First Lines and Richerand. In Chemistry, Webster's edition of Brande. In Surgery, Samuel Cooper's work, with his Surgical Dictionary as a book of reference. In Theory and Practice Dr. Good's Study of Medicine was adopted by Dr. James Jackson and generally followed. Gregory's Practice was often seen in the student's hands and Laennec's Treatise on Diseases of the Chest and their Physical Signs was just coming to their notice in the form of Dr. Forbes's Translation. Denman and Dewees were the favorites in their special branches. Bigelow's Sequel to the Pharmacopœia was much sought after by the students of this school. Like the excellent and serviceable work recently published by his successor in the Chair of Materia Medica, it was,

unpretentious enough for the most scrupulous teachers of the high and dry Northern latitudes.

Other works read by students were Hunter on the Blood, Fordyce on Fever, Heberden, and of course Cullen and the earlier standards which happened to be in their instructors' libraries. Louis was just beginning to be known among us. The Lectures of Sir Astley Cooper and of Mr. Abernethy were eagerly read. One fellow-student of mine read through the three solid quartos of Morgagni. These are the principal authorities I recall as lying about our study and lecture rooms. But my memory is, no doubt, sometimes at fault.

Great stories had been reaching us for some time of the schools and hospitals of Paris. Dr. John Jackson, nephew of our old Professor, came home with news of the fine opportunities there offered. Young James Jackson, the Professor's son, was there still, writing home letters which remain on published record, to show how much of talent, zeal, and high promise was lost to the Medical Profession by his early death. Especially did he speak of Louis, whom he had chosen as his principal teacher, and of whom he became the favorite pupil and the very dear friend. These circumstances decided me to seek the same centre of instruction, and so, in April, 1833, I left Boston to pursue my studies in Paris. Dr. John Jackson bade me farewell with a look as if I were indeed on my way to the good Bostonian's heaven, and handed me a small square of India-rubber, his own newly-suggested pleximeter, or instrument to be used for mediate percussion, which he wished me to show to Louis and the other great Paris doctors.

I have said something of my Boston teachers, and I will devote a few words to those whose instructions I followed in Paris, and to their most renowned professional contemporaries in other European countries, at the risk of some repetition of what I have said elsewhere.

Old Boyer, Baron Boyer, who, in spite of his title, kept his own books for sale at his own house, was still creeping around the wards of La Charité. At Hotel Dieu was the great surgeon Dupuytren. On the other side of the river was his large and loud rival, Lisfranc. Roux, best known by his report of his medical visits to England, was operating and lecturing, — lecturing, parenthesis within parenthesis, — ovum, germinal vesicle, germinal spot, until his embryo meaning vanished in the invisible; Velpeau, a reclaimed rustic, who by sturdy industry grew out of his wooden shoes into an erudite author and teacher and a celebrated practitioner; Civiale, the inventor of lithotripsy; Ricord, whose mercurial temperament, to say nothing of his practice, displayed itself in his lively clinical promenades; these were some of the more famous surgical celebrities of fifty years since. Louis, Andral, Chomel, Rostan, Trousseau, Bouillaud were the best known teachers of clinical medicine. Cruveilhier was Professor of Anatomy in the École de Médecine, and Orfila, the handsome Dean of the Faculty, lectured upon some branches of medical jurisprudence. Two or three water-logged old Professors were moored to their chairs; one of them not so very old, but with a good many ancient barnacles about him; one formidable three-decker, Broussais, with his upper tier of guns still above the water-line, and hanging away at the assails of his famous "physiological doctrine." Some of the specialists I recall were Sichel in ophthalmology,

Bielt in dermatology, Dubois the younger, and a younger Baudelocque, inventor of a certain lemon-squeezer-like machine, about as threatening to the future of the race as the invention of that other medical practitioner, Dr. Guillotin.

The works in the hands of French students were those of the great teachers and practitioners just mentioned. Jules Cloquet's Anatomy was a favorite manual. Sabatier's and Maygrier's were sometimes met with. The much more extensive and thorough work of Cruveilhier was a little later to come into common use. The great work of the same author on Pathological Anatomy was of a still later date. Bourguery's magnificent, somewhat dandified Anatomy, if I may borrow this term, was in course of publication. Its showy figures were got up like opera dancers, primarily for anatomical study and secondarily for æsthetic gratification. Magendie's Physiology had replaced that of Richerand. Boyer was still a leading authority in Surgery. The name of Jean Louis Petit was frequently cited in the lectures of Marjolin, himself scarcely remembered at the present day. Bayle and Corvisart were giving place to Louis and Bouillaud. Laennec held his position as few inventors and discoverers can hope to do in the face of the after-comers who improve on their improvements.

What had been the most signal advances in the science and art of medicine between 1783 and 1833, the first half of the century we are considering?

In medical science the method of studying the human body by its constituent elements, — the *General Anatomy* of Bichat, — which is to common descriptive anatomy what geology is to geography, would still hold the first place if it could claim all that the microscope has done for it. It was at any rate a great onward movement, with far-reaching results for physiology and pathology.

Next to this would come the discoveries of Sir Charles Bell and Magendie of the distinct motor and sensitive functions of certain nerves and nerve-roots.

The most important practical achievement was the introduction of vaccination. I know that this practice has been and is even at the present day the subject of violent attacks and bitter prejudices. It is only very recently that our distinguished visitor — our fellow citizen, — by the female side, — the Right Honorable Sir Lyon Playfair, at home alike in the laboratory of science and when presiding over the deliberations of the British House of Commons, has had to defend it, — nobly and successfully he did it, — in that august assembly. There is always an unconvinced and irreclaimable minority. Those who believed not Moses and the Prophets would not believe though one rose from the dead to convince them. Most of us, I feel sure, are ready to say of Jenner's discovery, borrowing some of Luther's words about justification by faith, that vaccination is a test *stantis vel cadentis medicinæ*.

Laennec's invention of auscultation holds the next place to vaccination in the records of practical improvement during our first half century. The recognition of the affection of the kidneys known as "Bright's disease," and the separation of the too familiar and fatal malady, diphtheria, from those with which it was long confounded, are other notable advances made during the period in question.

If we compare the two half centuries, we may balance the following improvements against each other:

Against the discovery of the double nerve function the extended knowledge of the reflex function.

Against "General Anatomy," the Cell-doctrine, due to the discoveries made by the use of the achromatic microscope, to which we also owe the discovery of the minute organisms, so important in the history of disease.

Against vaccination we may offset surgical anæsthesia.

Against the stethoscope the medical thermometer.

We must divide the honors of lithotripsy and those of ovariectomy between the two periods.

The beneficent changes in the treatment of insanity effected by the earlier labors of Pinel and Esquirol have been admirably carried on in the more recent period.

Many other and not inconsiderable improvements in medical science and art had taken place in our first half century, as may be seen in Cuvier's Report on the Progress of the Natural Sciences. But the last fifty years have been not less richly productive. I can only indicate in the briefest manner some few among their acquisitions.

Modern scientific chemistry is a mystery to us who were brought up in the old school of pyrotechnic experimenters. It seems to us to make over its theories and its nomenclature about once in ten or twenty years. But that may be our ignorance. We know as much as this, that our Professors teach real and most valuable practical knowledge by making the student work, and work thoroughly, in the laboratory.

Physiology is a new science, we might almost say, since the perfecting of organic analysis, the invention of the achromatic microscope, and of the numerous instruments of precision which record the vital actions and conditions.

Anatomy has added the more exact study of regions and of sections to its earlier methods of investigation.

Operative surgery has of late years achieved its greatest triumph in the establishment of abdominal section as a legitimate and safe operation. First employed by an American surgeon, Dr. McDowell, of Kentucky, in 1809, in the hands of Spencer Wells and his contemporaries it has rescued and is rescuing hundreds of lives. Tenotomy by subcutaneous section is another new and valuable operation. Plastic surgery has learned to patch deformities as a skilful housewife patches a garment. Limbs which would have been sacrificed, are saved by improved methods of dressing, especially by the use of antiseptics. Resection of joints or of portions of the shaft of a bone has in many cases taken the place of amputation. Let me not forget the operation of paracentesis with aspiration of the thorax in acute pleurisy, as first practised by Dr. Henry Ingersoll Bowditch and Dr. Morrill Wyman. But enough has been said to show that the last half of our century has justified itself for existing. I shall return to some of these matters when speaking of the new edifice where they are to be the subjects of instruction.

In the prevention of disease the gain has been extraordinary. The germ-theory, alluded to as one of the results of the perfecting of the microscope, has done much to account for the phenomena of many diseases and to indicate the means of arresting their development. The recognition of domestic malaria as the frequent source of disease is of vast importance. The phrase "drain fever" has saved hundreds of lives.

It is harder to speak of medical practice — the treatment of internal diseases, fevers, visceral inflammations

and the like. The practice of drugging for its own sake, the fatal bequest of the English apothecary, or "general practitioner," whose profit was made on his medicines, had infected the medical profession of this country, as I believed, when some twenty and more years ago in guarded terms, often misquoted, I denounced it somewhat too epigrammatically for some of my friends of the Massachusetts Medical Society. Professor Gairdner of the University of Glasgow has recently used language much plainer than my innocent allusion to the probable effect of sinking a cargo of miscellaneous drugs among the fishes. It has been objected, he says, "that the Scottish graduate in medicine was not sufficiently conversant with the details of compounding and dispensing powders, and pills, and mixtures, and above all draughts (at 2s. 6d. a piece) to be taken two, three, four or five times a day; in other words, that he had not sufficiently mastered the technical details by which his neighbor, the English apothecary, was able to accomplish the great ideal of the 'surgery-boy' type—the dispensing of immense quantities of 'physic' in the most complicated prescriptions, to pass unquestioned down the willing throats of Her Majesty's lieges." There can be little doubt that the practice thus originating influenced the whole professional public of England to a very considerable extent, and through that public introduced the over-drugging system into her colonial dependencies and the States which some of these became. However this may be, great changes have taken place within the later decades of my remembrance in the practice of medicine. Bleeding is an almost unknown operation. Of the four great remedies of Dr. Holyoke's and Dr. James Jackson's time, antimony has fallen from grace, and calomel, instead of being next the apothecary's right hand, as the letter e is to the printer's, has gone to an upper shelf, where it may be supposed to repent of its misdeeds like Simeon Stylites. Cotton Mather had said a century and a half ago, "I am not sorry that autimonial emetics begin to be disused." He had said too, more rhetorically, "Mercury, we know thee: but we are afraid thou wilt kill us too, if we employ thee to kill them that kill us." This was a lively way of putting a thought long afterward made into a famous saying.

While old drugs and old methods have become obsolete, new drugs and new methods have come in to take their place. The first aphorism of Hippocrates, "Life is short, art is long," and so on, is a glittering generality. The second aphorism is one of daily practical application, never to be forgotten. "Not only must the physician attend properly to his own duties, but he must see that the patient, the attendants, and all the external conditions are properly ordered." As the over-employment of drugs gives way to juster views, the hygienic conditions and personal attendance on the patient are like to be better cared for. The less the patient is annoyed with over-medication,—painful and disgusting remedies,—the more tractable he is like to be, and the less likely to throw his medicine out of the window, where it will kill the chickens instead of the fishes. The more attention is like to be paid to air and cleanliness and comfort, the more to the kind of nourishment and the modes and times of giving it. In proportion as the work of the apothecary diminishes the cares of the nurse are called upon to render disease endurable by all the arts known to a skilful attendant. Little things mean a great deal in the sick room. "Will you have an orange or a fig?" said Dr. James

Jackson to a fine little boy now grown up to goodly stature, and whom I may be fortunate enough to recognize among my audience of to-day. "A fig," answered Master Theodore, with alacrity. "No fever there!" said the good Doctor, "or he would certainly have said an orange."

Now it is in just these little unimportant, all-important matters that a good nurse is of incalculable aid to the physician. And the growing conviction of the importance of thorough training of young women as nurses, is one of the most hopeful signs of medical advancement. So much has been done and is doing that the days of the Sairey Gamps and Betsey Prigs are numbered. I cannot help saying in this connection that the Registry of Nurses fortunately connected with the Boston Medical Library, itself of comparatively recent formation, is a blessing to our community which can hardly be over-estimated. What is there in the hour of anguish like the gentle presence, the quiet voice, the thoroughly trained and skilful hand of the woman who was meant by nature and has been taught by careful discipline to render those services which money tries to reward but only gratitude can repay? I have always felt that this was rather the vocation of woman than general medical, and especially surgical practice. Yet I myself followed a course of lectures given by the younger Madame Lachapelle in Paris, and if here and there an intrepid woman insists on taking by storm the fortress of medical education, I would have the gate flung open to her as if it were that of the citadel of Orleans and she were Joan of Arc returning from the field of victory. I have often wished that disease could be hunted by its professional antagonists in couples,—a doctor and a doctor's quick-witted wife making a joint visit and attacking the patient,—I mean the patient's malady, of course,—with their united capacities. For I am quite sure that there is a natural clairvoyance in a woman which would make her as much the superior of man in some particulars of diagnosis as she certainly is in distinguishing shades of color. Maury a suicide would have been prevented if the doctor's wife had visited the victim the day before it happened. She would have seen in the merchant's face his impending bankruptcy while her stupid husband was prescribing for his dyspepsia and indorsing his note; she would recognize the lovelorn maiden by an ill-adjusted ribbon—a line in the features,—a droop in the attitude,—a tone in the voice,—which mean nothing to him, and so the brook must be dragged to-morrow. The dual arrangement of which I have spoken is, I suppose, impracticable, but a woman's advice, I suspect, often determines her husband's prescription. Instead of a certain lecture on his own failings he gets a clinical lecture,—on the puzzling case, it may be, of a neighbor suffering from the complaint known to village nosology as "a complication of diseases," which her keen eyes see into as much better than his as they would through the eye of a small-sized needle. She will find the right end of a case to get hold of, and take the snarls out as she would out of a skein of thread or a ball of worsted which he would speedily have reduced to a hopeless tangle.

I trust I have not dwelt too long on this point, which grew out of my consideration of the great change that has so largely substituted the careful regulation of all the conditions surrounding the patient for the drugging system derived from the practice of the English "Apothecaries." Like the Father of

Medicine in the aphorism which I have quoted, we consider attention to these conditions entitled to precedence relatively to all active interference with the course of disease.

Yet we must not be ungrateful to the pharmacist for the useful agents, old and new, which he puts in our hands. Opium and cinchona appear in our modern pharmacopoeia with all their virtues, but freed by chemical skill of the qualities which most interfered with their utility. Mercury is no longer considered a panacea, but it is still trusted for important special services. Most of the remedial plants have yielded their essential principles to chemical analysis and have got rid of the useless portions which made them bulky and repulsive. Iodine, bromine, salicine in their various compounds have, within the present century conferred inestimable aid in the treatment of some of the most formidable diseases. Many other new remedies, such as carbolic acid, glycerine, chloral, have been added to the list of those which are of daily use in combating particular symptoms, or are adapted to certain exceptional conditions. The method of administering remedies by inhalation has been greatly extended, and the admirable invention of the process of subcutaneous injection, — a method, I may remark, tried upon himself and made the subject of a thesis by the late Dr. Enoch Hale, a graduate of this school, — has become next to etherization the most rapid and potent means of subduing pain and other forms of suffering. I need not speak of medical electricity, which has proved so serviceable in the treatment of nervous and muscular affections.

I despair of enumerating all the improvements which have been effected in the various specialties into which the practice of medicine has become subdivided within these twenty or thirty years. The ophthalmoscope, the improved ear speculum, the rhinoscope, the laryngoscope — hold out their mirrors to enlighten us, or open their mouths to proclaim their own value. Diagnosis has reached a wonderful degree of accuracy; prognosis has become a terrible kind of second-sight which is not always handled carefully enough; treatment gains a little with every decade. The history of therapeutics records a succession of marches and counter-marches, with a slight onward movement as the total result of every completed revolution; slight, but precious to humanity.

I cannot pass over the most encouraging fact of the growth of medical libraries. We have a right to congratulate ourselves on the prosperity of that which has sprung into existence in this city within the last few years. It seems to me to mark the beginning of a new era in the medical history of the city. But what can I say of the immense library formed, but always forming, at Washington, and how can I sufficiently praise the work of Dr. Billings and his associates, one of the results of which comes before us in that colossal catalogue which is one of the best proofs of the advancing civilization of the great Republic?

It was time for the Medical School of Harvard University, — of that Institution of which Massachusetts must always be proud so long as she has anything to be proud of, — it was time for this school to plant its chief edifice in a fairer position, and erect it on a broader foundation than those with which it has been so long obliged to be contented. Let us not be ungrateful to the memory of our earlier

benefactors; to the State for the grant which proved of such value in its time; to the individuals who gave land and money when the former buildings were constructed. But the little Mason Street building was long ago outgrown, and that which succeeded it had in turn become wholly insufficient for the needs of the School.

You will pass from beneath this hospitable roof to the new edifice in which as we trust many successive generations of medical students are to receive a large part of their instruction. As you enter its doors, as you survey its halls and lecture-rooms, its laboratories and their appliances, some of you may be ready to exclaim, What! All this to teach a student to cut off a limb or administer a potion?

The question is a natural one, and the answer is easy. The Art of Healing is supported, advanced, illuminated, by the various kinds of knowledge which are recognized as belonging to the Science of Medicine. And the Science of Medicine, like all other kinds of classified knowledge, is best taught, most easily and thoroughly learned when taught systematically, because facts are most clearly perceived and most firmly retained in the memory when presented in their serial relations. The teaching of the various branches included in a complete medical course requires ample provision for its multiplied exigencies.

You will enter or look into more amphitheatres and lecture-rooms than you might have thought were called for. But if you knew what it is to lecture and be lectured to in a room just emptied of its preceding audience, you would be thankful that any arrangement should prevent such an evil. The experimental physiologists tell us that a bird will live under a bell glass until he has substituted a large amount of carbonic acid for oxygen in the air of the bell glass. But if another bird is taken from the open air and put in with the first, the new-comer speedily dies. So when the class I was lecturing to was sitting in an atmosphere once breathed already, after I have seen head after head gently declining and one pair of eyes after another emptying themselves of intelligence, I have said, inaudibly, with the considerate self-restraint of Musidora's rural lover, —

Sleep on, dear youth; this does not mean that you are indolent, or that I am dull; it is the partial coma of commencing asphyxia.

You will see extensive apartments destined for the practical study of chemistry and of physiology. But these branches are no longer studied as of old by merely listening to lectures. The student must himself perform the analyses which he used to hear about. He must not be poisoned at his work, and therefore he will require a spacious and well-ventilated room to work in. You read but the other day of the death of an esteemed fellow-citizen from inhaling the vapors of a broken demijohn of a corrosive acid. You will be glad to see that every precaution is taken to insure the safety and health of our students.

Physiology, as now studied, involves the use of much delicate and complex machinery. You may remember the balance at which Sanctorius sat at his meals, so that when he had taken in a certain number of ounces the lightened table and more heavily-weighted philosopher gently parted company. You have heard, perhaps, of Pettenkofer's chamber, by means of which all the living processes of a human body are made to declare the total consumption and product during a

given period. Food and fuel supplied; work done. Never was the human body as a machine so understood; never did it give such an account of itself as it now does in the legible hand-writing of the cardiograph, the sphygmograph, the myograph, and other self-registering contrivances, with all of which the student of to-day is expected to be practically familiar.

I do not see any room marked on the plan of the new building as intended especially for the use of the microscope. But that a proper apartment will be assigned to this use I feel assured. I have referred to the modern achromatic microscope as having created a new era in Medical Science. I have no time to tell what it has done for Anatomy, Physiology, and Pathology, besides its great services in other departments of knowledge. But to those who have never seen its miracles I can give an illustration which they will find it hard to believe I did not borrow from some new Gulliver's Travels or from some Jules Verne's imagination. Yet what I shall say is the simplest truth in the world to any microscopic expert, and may be easily verified by any sceptic.

If we had to examine the structure of a human body by the naked eye, — or as I will venture to call it, *gymnoscopic* or rather *gymnopic* inspection, — it would make a great difference whether our subject were of the natural dimensions or whether he were a Liliputian, or a Brobdingnagian. We should lose sight of many particulars in the structure of the Liliputian which we easily detect in a man of the natural size. We should find many things plain enough in the Brobdingnagian which we do not notice in the man of ordinary dimensions on account of their minuteness. Thus, for instance, we should find that man is shingled all over, or tiled, if you will — covered with scales, more literally, just as a serpent is. The statue of Liberty, the arm of which the cast in the square at New York has made familiar to us, the statue of Carlo Borromeo at Milan, that of Bavaria, or the new statue of Germania, any one of these changed to flesh and blood would be a great source of knowledge to a gymnopic anatomist. You will observe that the naturalist could examine only a small portion of one of these colossal figures at a time. Of course the same thing is true of the microscopic man I am going to describe. He must be examined in small fragmentary portions.

The individual from whom we will suppose the portion under examination to have been taken was, we will say, of short stature; a little more than five feet two inches in height and weighing one hundred and twenty pounds. Our microscope, a rather powerful, but not extraordinarily powerful one, magnifies a thousand diameters. This fragment, then, thus magnified, represents an individual just one mile in height. He would ten times overtop the loftiest of the pyramids; twenty times the tallest of our steeples. He could bestride our good city from Long Wharf to Charles Street. His breadth and thickness being in proportion to his height, his weight would be 120,000,000,000 (one hundred and twenty thousand million) pounds, equal to sixty million tons. He could take our State House up as we should lift a paving stone and fling it into the waters beyond Boston Lighthouse, — cleaning out that palace of the people by a summary process quicker than the prætorian bauds of Domitian or Commodus would have cleaned out a Roman Senate Chamber that dared to have an opinion of its own. Such is the microscopic man as we see him piecemeal in that won-

derful instrument. It is the telescope of the microcosm, — the master-key to the portals of a new universe, and the student must be carefully taught how to use it.

Among the various apartments destined to special uses one will be sure to rivet your attention; namely, the Anthropotomic Laboratory, known to plainer speech as the Dissecting Room. The most difficult work of a medical school is the proper teaching of practical anatomy. The pursuit of that vitally essential branch of professional knowledge has always been in the face of numerous obstacles. Superstition has arrayed all her hobgoblins against it. Popular prejudice has made the study embarrassing and even dangerous to those engaged in it. The surgical student was prohibited from obtaining the knowledge required in his profession and the surgeon was visited with crushing penalties for want of that necessary knowledge. Nothing is easier than to excite the odium of the ignorant against this branch of instruction and those who are engaged in it. It is the duty and interest of all intelligent members of the community to defend the anatomist and his place of labor against such appeals to ignorant passion as will interfere with this part of medical education, above all, against such inflammatory representations as may be expected to lead to mid-day mobs or midnight incendiarism.

The enlightened legislation of Massachusetts has long sanctioned the practice of dissection, and provided means for supplying the needs of anatomical instruction, which managed with decent privacy and discretion, have served the beneficent purpose intended by the wise and humane lawgivers without doing wrong to those natural sensibilities which are always to be respected.

During the long period in which I have been a Professor of Anatomy in this Medical School I have had abundant opportunities of knowing the zeal, the industry, the intelligence, the good order and propriety with which this practical department has been carried on. The labors superintended by the Demonstrator and his assistants are in their nature repulsive, and not free from risk of disease, though in both these respects modern chemistry has introduced great ameliorations. The student is breathing an air which unused senses would find insufferable. He has tasks to perform which the chambermaid and the stable-boy would shrink from undertaking. We cannot wonder that the sensitive Rousseau could not endure the atmosphere of the room in which he had begun a course of anatomical study. But we know that the great painters, Michel Angelo, Leonardo, Raphael, must have witnessed many careful dissections; and what they endured for art, our students can endure for science and humanity.

Among the large number of students who have worked in the department of which I am speaking during my long term of service, — nearly two thousand are on the catalogue as graduates, — there must have been some who were thoughtless, careless, unmindful of the proprieties. Something must be pardoned to the hardening effect of habit. Something must be forgiven to the light-heartedness of youth, which shows itself in scenes that would sadden and solemnize the unseasoned visitor. Even youthful womanhood has been known to forget itself in the midst of solemn surroundings. I well remember the complaint of Willis, a lover of the gentle sex, and not likely to have told a lie against a charming young person; — I quote from my rusty memory, but I believe correctly: —

She trifled! ay, that angel-maid,—
She trifled where the dead was laid.

Nor are older persons always so thoughtful and serious in the presence of mortality as it might be supposed they would show themselves. Some of us have encountered Congressional Committees attending the remains of distinguished functionaries to their distant place of burial. They generally bore up well under their bereavement. One might have expected to find them gathered in silent groups in the parlors of the Continental Hotel or the Brevoort House; to meet the grief-stricken members of the party smileless and sobbing as they sadly paced the corridors of Parker's, before they set off in a mournful and weeping procession. It was not so; Candor would have to confess that it was far otherwise; Charity would suggest that Curiosity should withdraw her eye from the key-hole; Humanity would try to excuse what she could not help witnessing; and a tear would fall from the blind eye of Oblivion and blot out their Hotel-bills forever.

You need not be surprised, then, if among this large number of young men there should have been now and then something to find fault with. Twice in the course of thirty-five years I have had occasion to rebuke the acts of individual students, once in the presence of the whole class, on the humane and manly sympathy of which I could always safely rely. I have been in the habit of considering myself at liberty to visit the department I am speaking of, though it had its own officers; I took a part in drawing up the original regulations which governed the methods of work; I have often found fault with individuals or small classes for a want of method and neatness which is too common in all such places. But in the face of all peccadillos and of the idle and baseless stories which have been circulated, I will say, as if from the chair which I no longer occupy, that the management of the difficult, delicate, and all-important branch committed to the care of a succession of laborious and conscientious Demonstrators, as I have known it through more than the third of a century, has been discreet, humane, faithful, and that the record of that department is most honorable to them and to the classes they have instructed.

But there are better things to think of and to speak of than the false and foolish stories to which we have been forced to listen. While the pitiable attempt has been making to excite the feelings of the ignorant against the School and the University, hundreds of sufferers throughout Christendom,—throughout civilization,—have been blessing the name of Boston and the Harvard Medical School as the source from which relief has reached them for one of the gravest injuries, and for one of the most distressing of human maladies. I witnessed many of the experiments by which the great surgeon who lately filled a chair in Harvard University has made the world his debtor. Those poor remains of mortality of which we have heard so much have been of more service to the human race than the souls once within them ever dreamed of conferring. Dr. Bigelow's repeated and searching investigations into the anatomy of the hip-joint showed him the band which formed the chief difficulty in reducing dislocations of the thigh. What Sir Astley Cooper and all the surgeons after him had failed to see, Dr. Bigelow detected. New rules for reduction of the dislocation were the consequence, and the terrible pulleys disappeared from the operating amphitheatre. Still more remarkable are the results obtained by Dr.

Bigelow in the saving of life and the lessening of suffering in the new method of operation for calculus. By the testimony of those renowned English surgeons, Sir Henry Thompson and Mr. Erichsen, by the award to Dr. Bigelow of a sexennial prize founded by the Marquis d'Argenteuil, and by general consent, this innovation is established as one of the great modern improvements in surgery. I saw the numerous and patient experiments by which that priceless improvement was effected, and I cannot stop to moan over a scrap of integument, said to have been made imperishable, when I remember that for every lifeless body which served for these experiments a hundred or a thousand living fellow-creatures have been saved from unutterable anguish, and many of them from premature death.

You will visit the noble hall soon to be filled with the collections left by the late Professor John Collins Warren, added to by other contributors, and to the care and increase of which the late Dr. John Jackson of precious memory gave many years of his always useful and laborious life. You may expect to find there a perfect golgotha of skulls, and a platoon of skeletons, open to the sight of all comers. You will find portions of every human organ. You will see bones softened by acid and tied in bow-knots; other bones burned until they are light as cork and whiter than ivory, yet still keeping their form; you will see sets of teeth from the stage of infancy to that of old age, and in every intermediate condition, exquisitely prepared and mounted; you will see preparations that once formed portions of living beings now carefully preserved to show their vessels and nerves; the organ of hearing exquisitely carved by French artists; you will find specimens of human integument, showing its constituent parts in different races; among the rest, that of the Ethiopian, with its cuticle or false skin, turned back to show that God gave him a true skin beneath it as white as our own. Some of these specimens are injected to shew their blood-vessels; some are preserved in alcohol; some are dried. There was formerly a small scrap, said to be human skin, which had been subjected to the tanning process, and which was not the least interesting of the series. I have not seen it for a good while, and it may have disappeared, as the cases might happen to be open while unscrupulous strangers were strolling through the Museum. If it has, the Curator will probably ask the next poor fellow who has his leg cut off for permission to have a portion of its integument turned into leather. He would not object, in all probability, especially if he were promised that a wallet for his pocket, or a slipper for his remaining foot, should be made from it.

There is no use in quarrelling with the specimens in a museum, because so many of them once formed a part of human beings. The British Government paid fifteen thousand pounds for the collection made by John Hunter, which is full of such relics. The Hunterian Museum is still a source of pride to every educated citizen of London. Our foreign visitors have already learned that the Warren Anatomical Museum is one of the sights worth seeing during their stay among us. Charles Dickens was greatly interested in looking through its treasures, and that intelligent and indefatigable hard worker, the Emperor of Brazil, inspected its wonders with as much curiosity as if he had been a Professor of Anatomy. May it ever remain sacred from harm in the noble hall of which it is about taking possession! If violence, excited by false

outcries, shall ever assail the treasure house of anthropology, we may tremble lest its next victim shall be the home of art, and, ignorant passions once aroused, the archives that hold the wealth of literature perish in a new Alexandrian conflagration. This is not a novel source of apprehension to the thoughtful. Education, religious, moral, intellectual, is the only safeguard against so fearful a future.

To one of the great interests of society, the education of those who are to be the guardians of its health, the stately edifice which opens its doors to us for the first time to-day is devoted. It is a lasting record of the spirit and confidence of the young men of the Medical Profession, who led their elders in the brave enterprise, an enduring proof of the liberality of the citizens of Boston and of friends beyond our narrow boundaries, a monument to the memory of those who, a hundred years ago, added a School of Medicine to our honored, cherished, revered University, and to all who have helped to sustain its usefulness and dignity through the century just completed.

It stands solid and four-square among the structures which are the pride of our New England Venice, — our beautiful metropolis, won by well-directed toil from the marshes and creeks and lagoons which were our inheritance from nature. The magnificent churches around it let in the sunshine through windows stained with the pictured legends of antiquity. The student of Nature is content with the white rays that show her just as she is; and if ever a building was full of light, — light from the north and the south; light from the east and the west; light from above, which the great concave mirror of sky pours down into it; this is such an edifice. The halls where Art teaches its lessons and those where the sister Sciences store their collections, the galleries that display the treasures of painting and sculpture, are close enough for agreeable companionship. It is probable that in due time the Public Library with its vast accumulations will be next-door neighbor to the new domicile of our old and venerated institution. And over all this region rise the tall landmarks which tell the dwellers in our streets and the traveller as he approaches that in the home of Science, Arts, and Letters the God of our Fathers is never forgotten, but that high above these shrines of earthly knowledge and beauty are lifted the towers and spires which are the symbols of human aspiration ever looking upward to Him, the Eternal, Immortal, Invisible.

SOME CASES OF HYSTERICAL AFFECTION OF VISION.¹

BY O. F. WADSWORTH, M. D.

THE four cases which I wish to report illustrate very different degrees and forms of visual disturbance. As the patients were all males, three boys and one adult, the cases also illustrate the fact, which ought not, indeed, to need illustration, but is perhaps not quite as generally recognized as it should be, that hysteria is by no means confined in its manifestations to the sex whose anatomical organization furnished the name. It is furthermore of interest that in three of these cases the only symptoms by which the affection was shown were such as were referred to the organ of

vision, while in the fourth case the ocular symptoms, though not the only, were yet the most prominent ones. Before we can venture to attempt anything like an exact explanation of the production of the phenomena observed in these, as in other cases, our knowledge of the nature and mechanism of hysteria must be far more advanced than it is at present.

In three of the cases the diagnosis was not difficult to make; in the remaining one, as will be seen, it was only through an unexpected accident that its nature was brought to light.

A boy of nine years of age, always well, not sensitive to pain, etc., as were some others of the family, while at school observed a blurring of the right eye, and felt as if the light troubled it. From that time he kept it shut and wore a bandage over it, but did not complain of pain, and answered questions as to pain rather indifferently. He went on at school for three or four days, using his left eye, and saying it did not hurt him to do so. In other respects he seemed perfectly well.

He was brought to me when the eye had been kept closed for six days. On removing the bandage there was no external sign of irritation, no appearance of spasmodic contraction of the orbicularis. He asserted, however, that he could not open the eye. By placing him in a shaded part of the room and proceeding slowly and carefully, it was possible to raise the lid without experiencing resistance, and while the lid was held open he was gradually encouraged to read the test types at the opposite side of the room. There was no congestion, the pupil reacted well, vision was $\frac{1}{2}$. He now allowed the lid to be held open while the eye was examined with oblique light, even once glancing round at the light during this process without showing any sensitiveness. Then he was able to hold the lid up himself while he underwent examination with the ophthalmoscope. This examination showed a normal fundus; but when it was over the lid drooped again over the eye. Further encouragement and the application of cold bathing to the lids for a few minutes enabled him to open the eye imperfectly, but in a hesitating way, as if he was still expecting some unpleasant result from the act. The condition was explained to the boy's father, and he went home with directions to use cold water bathing locally as needed. A few days later the father wrote that the eye was perfectly well.

A boy, eleven years of age, was brought to me from the western part of the State, July 1, 1880, with the following history: At four years of age he had scarlet fever, followed by general dropsy for some weeks, then pneumonia. After this there was digestive disturbance; for years he complained a little of stomach ache after two thirds of his meals. The last fall he had had a light attack of diphtheria, not followed by paralysis. After this again his digestion became worse; he had severe pain in the left hypochondrium, "so as to double him up," morning and night at about the same hour, and also occasionally during the day; he sometimes had nausea after food. His bowels were generally inclined to looseness, often he had a dejection after each meal. He improved on a diet mainly of meat and stale bread, and for the last three months had been much better and had little pain. The last summer he had complained for a time of pain in his eyes in the evening. Since the diphtheria he had complained of an ache in the eyes on reading, and if he did not stop the ache changed to a sharp pain. The eyes were never red.

¹ Read before the Boston Society for Medical Observation, October 1, 1883.

Sunlight and artificial light were troublesome. He had been kept from school all winter, and was much in the open air. He was now thin, but, his mother said, better in looks than for years, perhaps easily tired, but very active.

There was some slight roughness of the conjunctiva of the upper lids near the edge of the tarsus, not more than is often seen without special trouble. Vision of either eye was $\frac{1}{2}$. There was no insufficiency of the external muscles. In each eye the media and fundus were normal and refraction emmetropic. Without a glass he read .5 Snellen from 13" to 4", with +24 both farther and nearer, from 19" to 3 $\frac{1}{2}$ ". Even with these glasses, however, the eyes soon tired, sharp pain and blur came in a few minutes.

He was ordered citrate of quinine and iron; a collyrium of borax and camphor water; to read, with +24, three minutes three times daily, and to increase the time one minute each day. He returned home, and was to report progress.

July 6th his mother wrote that the day before, while celebrating the Fourth by the explosion of powder in a bottle, he had been burned, his hand cut, and his face speckled with powder; that the attending physician said the iris and pupil were not reached, but there were several grains of powder in the white of the eye.

September 21st his mother wrote again. For a week after the explosion he was unable to open his eyes at all, and was confined to a dark room nearly three weeks. As soon as the inflammation subsided he began to exercise the eyes as directed, "but to his utter astonishment and my own he found that he could read for an indefinite time without any of the painful sensations that he experienced before the accident, and he has now commenced school, and can even study in the evening (when before he could not even bear to sit in a room with a bright light), and his eyes are not at all affected unless when he becomes very tired and nervous, and then there is a slight ache." She added that I should have hardly prescribed such a blowing up as treatment, but that it had proved very effective.

Mr. —, aged thirty-four, employed in an importing house, in a position in which he had charge of a considerable correspondence, applied to me October 26, 1875, and gave the following history: During the winter of 1863 and 1864 he had malarial fever. In 1868 and 1869 he lived in New Jersey, and suffered from what he called "dumb ague," described as "a slight fever following an unpleasant feeling inside." Lately, on damp evenings, he had experienced a similar feeling while driving from the city to his home in the suburbs, and for this he was taking quinine in tonic doses. He was subject to headaches, chiefly about the brows; these he said were of three kinds, though all felt about the same, (1) those caused by use of the eyes; (2) "neuralgic," excited by an east wind, and generally to be warded off by a dose of guarana; (3) from the stomach, relieved by a Seidlitz powder. For the last year or two the heat of the sun had affected him much, and even so late in the season as the last part of October he could not walk in the sun without an unpleasant feeling in his head. He was thin and pale, but this was his usual habit.

His ocular symptoms were peculiar. For fifteen years he had known he was near-sighted. For nine years he had been unable to use his eyes in the evening. If he read in the evening he generally had a

headache the next morning, which lasted throughout the day. He was fond of music, but if he was exposed to bright light at a concert or assembly he had a headache the next morning but one, and for this reason he had for a long time refrained from such recreation. The last four years he had been unable to read print even in the daytime; reading print for only a few minutes caused headache, yet he could write and read writing without inconvenience; to read through a large foreign mail gave him no trouble.

It was evident from his statements alone that imagination must play an important part in the production of the symptoms.

The eyes were externally normal, and throughout their examination showed no special sensitiveness to light. Vision in the right eye, with —36, was $\frac{1}{2}$; in the left, with —24, $\frac{1}{2}$ to $\frac{1}{2}$. He read, without glasses, Snellen 1 $\frac{1}{2}$ at 22" and up to 7 $\frac{1}{2}$ "; with the refraction equalized by placing —72 before the left eye the print appeared clearer. There was no insufficiency of the muscles at 15". The fundus of both eyes was normal.

He was encouraged that his disability could be removed, and advised to continue the quinine, and to take moderate exercise. Glasses to correct his myopia were to be worn except while at work, and for reading and writing he was to wear a plane glass right, —72 left. He was directed to read print for five minutes three times daily, always at the same hour, to increase the time of reading one minute each day, and to report in ten days.

November 6th he returned, bringing with him a memorandum of the time and amount of the reading done each day, with careful notes of his sensations. I regret that these memoranda have been lost or mislaid so that I am unable to give them verbatim. He had had several times dull pain in the brow after reading, and had omitted reading several times from dread of increasing this pain. He was again encouraged, told to begin now with seven minutes' reading, and to increase gradually as before. He was to persist in the readings without regard to the headache, and on no account to interrupt them without reporting to me immediately; in any case to return in a week.

This time he followed out the directions thoroughly, and it was interesting to observe from his memoranda how carefully he had watched his symptoms, and how, as he became convinced they were not serious, the headache first did not increase with continuance of the reading, then ceased altogether. His progress was now steady and uninterrupted; after a while he was allowed to increase the length of his reading more rapidly, and ten weeks from the time of his first visit he was dismissed from treatment, being able to read as he pleased, in the evening as well as in the daytime, and having attended an oratorio at the Music Hall without any subsequent discomfort. I have seen him at intervals since then, and there has been no relapse.

William C., aged twelve, came to the Out-Patient Department of the Massachusetts General Hospital January 3, 1879. He was the tenth of a family of eleven children, of whom six were living. According to the mother's statement four had died of phthisis and one of brain disease, all below the age of three years. An older sister had been under the care of Dr. J. J. Putnam with hysterical symptoms. The boy's own history was as follows: About two years before

he apparently began to grow very near-sighted. This was first noticed by his teacher at school, and it had reached such a degree that he held his book so near his face that what he read could not be understood. He even stated that he could not see to read unless his nose actually touched the paper. With the near-sightedness there had come a marked change in his temperament. While he was formerly tractable, and his earlier teachers remembered him as a good boy, he had in the last two years become obstinate and troublesome. He continued at school till the last fall; then had a "row" with the teacher, and ran out of the school. For a year his appetite had been failing. For the past three months vomiting had been a prominent symptom, occurring nearly every other day before breakfast, and he was never able to eat his breakfast until he had been out into the air. At one time, three or four weeks before I saw him, he had gone two days without food. Of late he had had bad dreams; that he was being killed, etc. He was waked every morning at three or four o'clock by a sharp pain in his eyes. He said that his sight was worse at night, and that one reason why he did not wish to go to school was that other boys called him "blind" in the evening, and also "color-blind." His sister stated that he stumbled over objects at home, where he was familiar with the locality, as if he did not see them, yet he always wanted a hat with a broad brim to protect his eyes.

He was of good height for his age, but slightly built, pale and anæmic in appearance, thin in flesh, his manner somewhat apathetic. The eyes were externally normal; the pupils reacted well. With the right eye he read X at 2' to 2½'; with the left eye XII at the same distance. No glasses improved his vision. There was no abnormal decrease of vision when the light was diminished. With the right eye he distinguished green, red, pink, and blue, but could not tell yellow. With the left eye he recognized red, pink, and blue, but neither green nor yellow. A few minutes later he told yellow, as well as the other colors, with the right eye; still neither green nor yellow with the left.

The field of vision was much and concentrically contracted; it extended nearly equally in all directions from the fixation point, having at the distance of a foot a diameter of 6" to 6½"; it was very nearly alike in the two eyes. The ophthalmoscope showed the refraction to be emmetropic, the media clear, the fundus everywhere quite normal in appearance. Even when the pupils were dilated by atropine careful examination detected no anomaly. This condition, a perfectly normal fundus, was repeatedly found so long as the case was under observation.

Cod-liver oil was prescribed, and general hygienic directions given.

January 7th his sister reported that before taking the cod-liver oil he would say there was a fish in the tumbler, and insist upon rinsing it repeatedly. His vision was not as good as on the 3d; he now read VIII at 10" with difficulty. The field of vision also was smaller, averaging about 3" at a distance of one foot. It was also measured at a distance of three feet, and the results corresponded fairly well.

January 14th he read IV at 7"; told all colors with either eye, but required several seconds to recognize them. The field of vision, tested by the moving hand while the eye of the observer served as the object of fixation, seemed a little smaller than on the 7th.

January 21st pills of sulphate of strychnia, one

twelfth grain three times a day, were ordered, but as he showed the physiological effect after taking the second pill they were reduced to two per diem.

January 23d he told all colors at 1', but could recognize none at 2', even against a white background.

January 30th the field of vision, measured on the blackboard, was only 2" in diameter at 1'. When he fixed my eye while I moved my hand slowly toward the line of vision, giving it at the same time a constant lateral motion, the hand often reached or even crossed the line of vision before he admitted that he saw it. This phenomenon was observed several times at later dates, and he sometimes even asserted that he could not see the hand when it was kept in motion in a position directly between his eye and mine. The strychnia was now omitted and iron given.

By March 20th the boy's color was improved. His vision the same.

April 24th he had a fair color, and his general appearance was better; his sister said he had never looked so well. He read III at 7"; his field of vision was 3" in diameter at 1'; he told colors correctly at 2'. Though measurement on the blackboard showed so contracted a field, it was noticed while testing his color sense that when a bit of colored paper fell from my hand to the ground, the hand being at the time much outside the asserted field, the boy's eyes turned down to follow the paper, as if the size of the field were normal.

He continued the iron and cod-liver oil till June, and then went into the country, where he stayed till September. At the end of September he stated that he had improved in sight and in general condition, but still was troubled by night-blindness. He had a scar across his nose, the result of a fall over something in the dark, and by his sister's statement he fell in the dark frequently. He told letters of VIII at 12" with difficulty, soon after at 18". The field, at 1', had a diameter of 6" to 8" in either eye.

He was lost sight of till July, 1880, when he came on account of a slight conjunctivitis. He was said to have improved in general health, but in other respects to have changed little. His field of vision, tested with the hand, was only 1" to 2" in diameter. Yet he had now for six weeks been serving as a messenger boy in a district telegraph office, liked the employment, and found no difficulty in going about. In fact, from the first, whenever he was under my observation he had shown plainly from the manner in which he moved about that no very great actual contraction of the field could exist. How much of the simulation was conscious, how much unconscious, it is difficult to say.

About a year later I met the boy in the street; he had grown, and looked in good health; he told me that his sight had become normal in all respects.

A SUCCESSFUL CASE OF TETANUS NEONATORUM TREATED WITH BROMIDE OF POTASSIUM.

BY L. EMMETT HOLT, A. M., M. D., NEW YORK,
Attending Physician to the Northwestern Dispensary in the Department of Diseases of Children.

RECOVERY in cases of tetanus of the newly born is rare. Bad as the prognosis of this disease is in adult life, it is even worse in the young child. The most frequent cause of death at all ages being exhaustion, it

is easy to see why the child of a few days readily succumbs.

The earlier writers upon tetanus neonatorum held it to be absolutely fatal. More recent ones hold out but little encouragement from their experience in its management. Thus Vogel lost all of his cases. Of twenty-four observed by Finkh none survived. In Stockholm, where the disease is very common, Cederchjoeld saw forty-four cases with but two recoveries. Every one of one hundred and eighty-five cases occurring on the Island of Heimacy about the beginning of this century died. Dr. J. Lewis Smith in his excellent article on this subject in the last edition of his *Diseases of Children* states that only one instance of recovery has come under his observation; though he mentions eight cases collected from various sources.

Among the negro children at the South the disease was formerly very prevalent, and Nailor¹ says that it was so uniformly fatal that a physician was never called.

The following case is published, not with the idea of proposing bromide of potassium as a specific for the disease, but as furnishing an instance of very prompt and very decided improvement under its use, and also illustrating the remarkable tolerance of this drug in young infants.

Katie M., aged seventeen days, was brought to the dispensary by the mother September 27, 1882. She gave the following history: 'The child was born at full term, the labor being very easy, and of only two or three hours' duration. The cord fell off on the fourth day, but the umbilicus has not yet quite healed. There had been no hæmorrhage from this source. Except this condition of the umbilicus, and quite a severe eczema which had developed about the genitals and inner surfaces of the thighs, nothing abnormal had been observed about the child until it was twelve days old. Then the mother noticed that it would occasionally straighten back while nursing and become very rigid for a few moments. Sometimes it would get black in the face at these attacks. Soon after it was seen to open the mouth with difficulty and not to the full extent. Since that time these paroxysms had become gradually more frequent and more severe, and even between them the body was very stiff. Nursing had become impossible, and the child had been fed with a spoon for four days. Urine and bowels were reported regular. There had been no fever noticed. The hygienic surroundings, it was afterwards learned, were about as unfavorable as they could well be in a tenement house, though the child showed no evidence of neglect in its person.

On examination I found a tolerably well-nourished child. It lay upon the back, the body being slightly arched in opisthotonos. The upper extremities could be moved somewhat, though the fingers were tightly flexed and the thumbs held between the first and middle fingers on each side. The lower extremities were almost completely extended and perfectly rigid, no motion being allowed at hips or knees. The skin was loose and flabby, and the hard contracted muscles beneath gave the limbs a peculiar feeling. There was an eczema over thighs, genitals, and lower part of abdomen, for the most part dry, but in places still exuding moisture. The whole integument of this region was greatly reddened. The umbilicus itself was a little pouting, and presented a small excoriated surface, hardly amounting to an ulcer. There was no sign of

suppuration. The face presented a singular aspect; the muscles of the jaws stood out rigidly. The jaws could be separated barely enough to admit the little finger between the gums. The eyes were closed and lips pouting.

The child cried with a low whine much of the time. Every few minutes a paroxysm would come on; then the muscles of the face became more rigid, the respiration ceased for the time, the face was cyanotic, and the extremities even more rigid than before. This passed off in a few moments, and nothing but the tonic rigidity remained, but this was enough to enable the child to be balanced upon the hand like a piece of wood. Rectal temperature 99½° F.

Ordered ten drops of brandy every two hours, and potass. bromid., four grains, every three hours; the umbilicus to be dressed with simple cerate.

September 28th. By mistake double the dose of bromide was given each time, but as the child seems to have suffered no bad effects the larger doses are ordered to be continued. The breast milk, given with a spoon, was taken well and retained, as was also the brandy. Condition about the same as yesterday.

September 29th. There is decided improvement in the symptoms. The medicine has been given regularly night and day. There is not so much rigidity of the lower extremities, and the mouth can be opened a little better. The cry is stronger. The child nursed three or four times during the past night, this being the first time for a week. The bowels are a little loose, and vomiting took place once to-day. The child sleeps most of the time. Rectal temperature 99¾° F. The treatment is continued. The umbilicus has been dressed with ungt. zinc. oxid. It is healing.

September 30th. Nurses so well that hand feeding is discontinued. Has been more restless and worrying a good deal to-day, but the paroxysms are not so frequent. Temperature 99¼° F.

October 2d. The umbilicus has about healed. Has slept most of the past twenty-four hours, and during this time has been almost completely relaxed. The rigidity has almost gone. Temperature 101½° F. The bromide is reduced to five grains every three hours. Brandy continued as before.

October 3d. Only a few mild paroxysms during the night, but high fever is reported to have been present. Temperature 100½° F.

October 4th. The child is not quite so well to-day. The paroxysms have become more frequent and more severe than for several days. It has scarcely slept at all. Quite a severe paroxysm is witnessed to-day; this is almost as marked as at any time during the disease. Relaxation in the interval seems complete, however. Bromide again increased to first doses of eight grains every three hours.

October 5th. A few mild paroxysms between two and four this morning, otherwise quiet.

October 18th. No paroxysms have occurred since the 5th instant. The bromide has been gradually diminished, and is now stopped altogether. The child is gaining flesh, and the eczema is very much alleviated. A small hernia has formed at the umbilicus, but otherwise everything here is normal.

Discharged cured.

February 10, 1883. I saw the child to-day, and learned there had been no further manifestations of the disease since it was dismissed from treatment.

Remarks. I have before me notes of fifteen other

¹ New Orleans Medical Journal, 1846.

cases of recovery from tetanus neonatorum, reports of which I have found scattered through medical literature. The following are the methods of treatment so far as they have been given: "Castor oil and local sedatives;" quinine and morphia endermically, nothing by the mouth; Cannabis Indica in full doses, that is, one half ounce of the tincture per diem; ipecac and quinine in small and frequent doses; atropia hypodermically; sulphate of zinc in five-grain doses every three hours, and "a little opium;" chloral in doses of one grain or two grains four or five times a day; postural treatment alone, no medication.

From this array of facts it is evident that we must not be too ready to draw conclusions with regard to the action of drugs in this disease. Hasty conclusions from insufficient data are among the most serious obstacles to progress in therapeutics. We Americans are especially open to this charge.

It seems to us that we may divide the cases of tetanus into three groups:—

(1.) Those acute severe cases which prove fatal in from one to three days in spite of all treatment. This class includes, unfortunately, the great majority of the cases.

(2.) The very mild ones, which tend to a spontaneous recovery. In this class, it would seem from the histories, that several of the fifteen cases referred to belong.

(3.) Those which are less acute than the first series, but still severe, in which recovery seems to be due to the treatment employed.

We should class our own case among the last mentioned.

Up to the beginning of the treatment the case had been growing steadily worse. Eight grains of the bromide were taken every three hours, night and day, for five days. Inside of thirty-six hours there was such improvement that the child took the breast for the first time in a week. At the end of five days, when the child was so much better that the dose was reduced, a decided exacerbation in the symptoms followed, which lasted until the larger doses were resumed.

The brandy, no doubt, contributed to the favorable result, and is to be advised as an accessory to all modes of treatment.

The view advocated by Dr. Marion Sims in 1846, that this form of tetanus is frequently, if not always, due to pressure from displaced cranial bones, has not been sustained by subsequent experience. Latterly almost all forms of treatment have been abandoned except that by motor depressants of the spinal cord. Among these drugs chloral undoubtedly holds the first place in the minds of the majority of observers. Any drug to be of service must be pushed to its full physiological effect. Since this principle has been appreciated recoveries in tetanus have multiplied quite rapidly.

That the bromides are safer than chloral needs no argument here. This case shows that they are tolerated in young infants to a remarkable degree. I have been unable to find that they have ever been thoroughly tried in tetanus neonatorum in the doses indicated.

This case is submitted with the hope that others may be led to test the drug in future cases to see whether after all we have not in the bromide of potassium a remedy fully as efficient as chloral, and much safer.

Reports of Societies.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. W. SWAN, M. D., SECRETARY.

NOVEMBER 11, 1882. DR. MINOT read a paper on the

HYGIENE OF THE LYING-IN ROOM.¹

DR. INGALLS remarked upon the impossibility, in many cases, of carrying out the regulations proposed by Dr. Minot, admirable and clearly stated as they are. It was important, no doubt, that the room, etc., *should* be so arranged, but in what proportion of cases *could* it be done? The moment the physician began to propose this beneficial arrangement he was met by the statement "Well, I'll do the best I can," and this means that many of the behests are looked upon as unnecessary, therefore unattempted.

DR. MORRILL WYMAN remarked that the slip of board placed on the inside of the sash (not under it), and held by the window frame, so that it can turn on one of its long sides, gives an upward or downward direction to the incoming air, and prevents direct draughts, while the amount of air is controlled by raising or lowering the sash outside the board. It can be fitted to the bottom or top of the window, when both sashes are movable, as they ought always to be in a sick room.

Change of clothing, the introduction of fresh air and sunlight, he said, had more effect in securing the results of disinfection of a sick room than the diffusion of carbolic-acid vapor.

According to the investigations of Sternberg, carbolic acid was of no use as a disinfectant (except as occasioning a free use of water) unless used with caustic strength.

DR. J. STEDMAN reported, in connection with this subject, a case illustrating the necessity of the arrangements suggested by Dr. Minot. The patient had hired a large house for the summer. As the patient had chronic trouble with the kidneys and her general health was not good, the precaution was taken to investigate the plumbing, and a leak was found in the bath-room. This room opened into the dressing room, and that into the lying-in room. It was further found that the main soil-pipe was of lead and completely honeycombed, and the connections so broken that the foul air from the cess-pool had complete access to the lying-in room. The necessary repairs were made, and the patient was confined at term and did well.

The following year a student at the Harvard Medical School occupied a room over a brick drain in another part of the same house, and had typhoid fever, with severe hæmorrhage, and died in consequence.

Dr. Stedman further reported the case of a lady living in a modern house, whom he attended in confinement. She was delivered without accident. Dr. Stedman noticed that the bath-room door opened into the patient's bed-room, and accordingly had the door locked and the key put away. At the end of a week the patient had a severe chill, with copious vomiting of dark grumous blood, and in three days she died. She had been seen by Dr. Ellis in consultation, and on the same day an investigation showed that the sewerage was very defective, that the pipes from this and the

¹ See page 343, JOURNAL of October 11, 1883.

adjoining house joined at a distance of twenty feet, the common duct leading to a cess-pool ten feet in diameter made in the solid rock, and furnished with a cover which was sealed on. Thus resulted a pneumatic apparatus, the effect of which was that when sewage was let on from one house the air of the cess-pool was driven up into the other house, and *vice versa*; and there was, what was worse, a hopper in each cellar for the servants. The landlord refused to believe that the condition of the drainage was the cause of the lady's sickness, but the Board of Health ordered communications to be made with the common sewer.

DR. GREEN reported a case occurring during the past summer which illustrated the difficulty of getting patients to do as they should. This patient was a primipara who had not been in very good condition throughout her pregnancy. She had the choice of all the rooms in the house, but could not be prevailed upon to take one down-stairs, but insisted upon being at the top of the house in a chamber where there was a set bowl which was not even trapped. Thus there were three adverse factors in the case: the previous poor condition, an unwillingness to follow good advice as to taking care of herself, and the untrapped set bowl. She had a tolerably serious labor, and was delivered by forceps, escaping perineal laceration. Twenty-eight hours after labor she had a chill, followed by a temperature of 103° F., and rapidly developed symptoms of septicæmia, of which she died on the eighth day.

DR. GREEN spoke of the imperfect means by which, in most city houses, cold air is supplied to the furnace as a not improbable cause of zymotic disease. The cold-air box, he said, is commonly constructed of wood, runs beneath the basement floor through a sub-cellar three or four feet deep, and opens at, or just below, the surface of the ground. Even if the outer opening of the box is covered with a proper grating so that cats cannot enter, the wooden box is often gnawed into by rats, which sometimes die there. Moreover, the holes thus made afford ingress to the air of the sub-cellar, which may be more or less noxious either from a defect in the house drain which traverses the cellar, or from the broken and leaky drain of a neighboring house. The air, too, which enters the box from without near the level of the ground is liable to be contaminated with effluvia from cats and garbage barrels in the back yard, or from the top-dressing commonly placed on the grass plat at the front of the house. This impure air thus introduced to the furnace is thoroughly heated, a condition well adapted for the development of any germs contained in it, and then distributed to the living and sleeping rooms.

Every room, especially, as Dr. Minot has said, the lying-in room, should have an open fire both to heat and to ventilate it, but it is usually necessary to supplement the open fire with furnace-heated air, and that this may be as pure as possible the following conditions are essential:—

- (1.) The cold-air conductor should be made of galvanized iron or of glazed drain pipe of large diameter.
- (2.) After emerging from the house wall the conductor should be built up fifteen feet or sufficiently high to receive unobstructed currents of air. There should be properly grated openings on three sides near the top, and a suitable damper to regulate the entrance of air.
- (3.) The sub-cellar should be ventilated by means of a large pipe opening into a hot chimney flue.

DR. MINOT thought that ventilation of a soil pipe into a chimney was very objectionable. Although there might always be an upward draught while the chimney was warm, yet when the chimney was cold there would probably be a downward draught. He alluded to a case which he had lately seen, in which the ventilating pipe was introduced into the flue of the parlor fire-place. A suspicious odor led to an examination of the drainage, and on applying the usual test the parlor was filled with the smell of peppermint.

PLACENTA PRÆVIA WITH CHRONIC BRIGHT'S DISEASE.

7 A case in the practice of Dr. S. T. Harmon, of Boston, reported by him, and read by Dr. INGALLS.

R. S. G., aged thirty-three, multipara, had first symptoms of kidney trouble four years ago. During the pregnancy under consideration everything went well up to the night of October 4, 1882, which was about the end of the eighth month, when she was suddenly awakened from a sound sleep by blood running down her thighs.

Dr. H. was called at one P. M., and found the patient cold and faint, with rapid pulse, etc.; no labor pains; the os was reached with great difficulty; it was open to the size of a twenty cent piece, and the placenta was attached so as to half cover the circle; the hæmorrhage was slight at this time.

By external manipulation and palpation a diagnosis of pelvic presentation was made, and at four A. M., 4th October, Dr. William Ingalls saw the case and advised the insertion of a large tampon, to be removed in six hours, and changed *pro re nata*; and also enjoined quietude and watchfulness on the part of the attendants. Patient was kept quietly in bed, opium given moderately, and tampons changed; this plan of treatment was followed for three days, and in the afternoon of the third day, October 7th, the tampon was removed.

About midnight of the same day the patient had another accession of flooding, together with labor pains, but upon investigation it was concluded that the membranes had ruptured, the liquor amnii had escaped, and that the loss of blood at this hæmorrhage had been slight.

Dr. Ingalls saw the case again, and dilatation and delivery were determined on.

Dr. Ingalls began with ether shortly after three A. M., about seventy-four hours after first flowing, and it was many minutes before the patient was fairly under its influence. The speaker removed the tampon, there being considerable hæmorrhage at this time, and introduced his hand into the vagina. The head presented. The cervix was dilated manually, and in a short time the hand could be introduced into the uterus. At this time Dr. Ingalls completed the dilatation to the size of his closed fist, turned the child, and delivered at about 3.45 o'clock A. M. The child was revived after some difficulty. He was well developed. The placenta was expressed shortly afterwards, and ergotine given subcutaneously. There was little or no hæmorrhage at this time. Patient did very well save for troublesome after-pains, which lasted about three days. The child had temporary paralysis of the left arm for nearly two weeks, but is now well and healthy in all respects. The mother resumed household duties in two weeks.

At the time labor came on the patient was troubled with dizziness, nausea, with occasional vomiting, and considerable diarrhœa. The eyelids were puffy, and

legs œdematous. The urine had one per cent. of albumen, hyaline, fine and coarse granular casts, etc.

DR. SINCLAIR said he thought the case was admirably conducted, but that for himself he would have delivered the patient then and there without waiting for a worse condition.

DR. RICHARDSON believed that the only way to treat the case was by immediate delivery; that it was safer to do the operation at once when the patient was in good condition. Upon this plan, and by a method previously detailed, he had had eleven cases, in all of which the patients had lived. In the last number of the *American Journal of Obstetrics* is an abstract of an article by a German author, who had saved a large proportion of cases by this method.

DR. TOWNSEND asked Dr. Richardson what course he would take in the case of a patient in the sixth or seventh month of pregnancy with hæmorrhages, sometimes a pretty alarming one.

DR. RICHARDSON replied that he would first make up his mind as to a diagnosis if the case were not earlier than the seventh month. At the sixth month it might not be possible.

DR. DOE stated that, as regards early hæmorrhage, he had the day before attended in her first confinement a lady, thirty-eight years of age, who last July had had hæmorrhage, and her physician in the country had diagnosed placenta prævia. In August the result of examination was unsatisfactory, but it was thought that on the right side of the cervix the placenta could be felt. From that time occasional hæmorrhage recurred. Ten days ago it could be ascertained that the placenta was lying close up to the os, but not overlapping it. Labor set in with spontaneous rupture of the membranes, and an examination soon after showed the head to be pressing firmly down upon the internal os. There was no undue hæmorrhage throughout the labor. The cervix dilated easily, but the labor had to be completed by forceps, on account of inefficient expulsive pains.

DR. RICHARDSON said his remarks were hardly intended to apply to a case like that reported by Dr. Doe, where the attachment was marginal.

DR. RICHARDSON said that he was called in consultation to see a lady who had been suddenly taken with flowing. The placenta was wholly over the os, which in the course of an hour had dilated from a condition which would admit only the tip of the finger to the size of a silver dollar. He stated to the attending physician that he would have no objection to putting in a tampon provided the patient were carefully watched. About twenty-four hours later he was called again, and was met by the statement that the tampon had prevented any further loss of blood, but upon looking at the patient it was evident that she was dying from internal hæmorrhage. The os was found fully dilated, and the patient was at once delivered by version, but soon died of exhaustion from the internal hæmorrhage. The child was of course dead. In this case the patient should have been delivered at once, or if the tampon had been applied the woman should have been unceasingly watched for evidences of internal hæmorrhage. In reply to remarks by Dr. Reynolds, Dr. Richardson stated that if one had a case of placenta prævia and the child were viable it was impossible to foretell the occurrence of a hæmorrhage which might end the case. In an instance cited first there was almost no hæmorrhage, then occurred a tremendous flow, and the woman was

considered dead. The heart, however, had not ceased to beat; the patient was rapidly delivered by version, and she recovered. Dr. Richardson did not think alarming hæmorrhage from placenta prævia was likely to occur before the child was viable, — say before the seventh month.

DR. SINCLAIR recalled one case of dangerous hæmorrhage at the fifth month, the patient flowing so that it was found necessary to deliver her. The uterus was found to contain twins. The circumstances of the case may have been due to the fact that the uterus was considerably larger than it would have been with a single fœtus.

PSEUDO-MEMBRANOUS ENTERITIS.

DR. BOARDMAN asked an opinion as to the conditions under which pseudo-membranous enteritis occurred. He referred to several cases once reported to the Society for Medical Observation by Dr. Goss, in the discussion following which Dr. Boardman had made the observation that the condition was never found except in hysterical subjects, but that the origin of the phenomenon had never been explained. Since these cases had been reported he had had two examples, one in a married woman, thirty-five years old, the subject of chronic hysteria. Dr. Boardman had expressed the belief to her that after the menopause the symptoms would disappear. The other case, however, was that of a woman fifty years old, who has been under the care of a number of physicians for a period of fifteen years. She now has, and, according to her report, has had for a number of years, this pseudo-membranous discharge from the bowels. She was said to have had uterine prolapse, inflamed and enlarged ovaries, some trouble with the coccyx, etc., and her husband had been consulted at different times as to the removal of the ovaries, the coccyx, etc. She had had her perinæum sewed up, and the operation was followed by phlebitis in the left leg. Pressure upon the left ovary, which can readily be felt, is borne without pain. The right ovary has atrophied. The only disease is the hysterical condition, with some debility and anæmia, and the abnormal product of the bowels. Dr. Boardman exhibited to the Society a specimen of the discharge from this patient.

HOURLY CONTRACTION OF THE UTERUS.

DR. J. STEDMAN said that he had seen two or three examples of this condition, one of which was that of a woman to whom he had been called in consultation, the placenta not having come away. Two fingers were passed through the internal os, and after some time there was encountered a central uterine constriction, which, after a dilatation for about an hour and a half, allowed the hand to pass and seize the placenta, when the hand, placenta and all, were expelled by the uterine contractions. The constricting ring instead of being circular was transversely elliptical, and the uterus itself was very movable and hard to fix. Some, but not alarming, hæmorrhage occurred. It was not deemed wise to put the patient under ether, but she bore the operation remarkably, and has since done well.

DR. RICHARDSON said he believed that anæsthetics greatly predisposed to hæmorrhage. The only hæmorrhages that he had ever seen had followed the use of ether.

DR. SINCLAIR said he had declared more than eight-

een years ago that the use of ether predisposed to hæmorrhage.

DR. MINOT stated that the only fatal case of post-partum hæmorrhage he had ever had in his own practice was that of a patient who had taken no ether or other anæsthetic.

DR. RICHARDSON detailed two cases of hæmorrhage in Dublin, following the use of chloroform.

DR. WYMAN [not Lyman] asked if it were not an accepted fact that full etherization usually diminishes the force of the uterine contractions, and if so should it not be used with caution in cases where uterine hæmorrhage is feared?

DR. RICHARDSON, having some reference to remarks just made by Dr. Reynolds, asked if Dr. Reynolds would give ether to the nagging pains in the first stage, and spoke of the extraordinary value of chloral hydrate, given in doses of fifteen grains every twenty minutes, till forty-five grains had been taken, in relieving the pains of the first stage, and with such regularity that the administration had become almost a routine practice at the Boston Lying-in Hospital as well as in his own private practice. In regard to ether, the principle was that, as already suggested by Dr. Wyman, by diminishing the force of uterine contraction it increased the danger of hæmorrhage.

DR. BOARDMAN stated that, given in the usual manner, he had found ether to exert a favorable influence upon the progress of the case. He thought, too, there might be a fallacy in the reasoning of Dr. Richardson, in that his opinion was based upon cases in which some operative measures were required, when the hæmorrhage might have been due, either to the operation alone or to the customary deep anæsthesia, or to both combined.

MASSACHUSETTS MEDICAL SOCIETY.

COUNCILORS' MEETING.

THE fall meeting of the Councilors was held at the Medical Library, Boston, on Wednesday, October 3, 1883. The meeting was called to order at eleven A. M. by the President, Dr. Alfred Hosmer.

DELEGATES, ETC.

Delegates were appointed to the meetings of the State Medical Societies of Vermont and New York. To the former, Drs. Goddard, of Orange, and Driver, of Cambridge; to the latter, Drs. Crowell, of Haverhill, and Babbitt, of North Adams.

Dues were remitted to several Fellows, in accordance with the recommendation of the Committee on Finance, and other Fellows were allowed to resign, retire, or were dropped from the roll, as recommended by the Committee on Membership and Resignations.

REPORT ON SPECIAL MEETINGS OF BOARDS OF CENSORS.

Dr. E. H. Bradford, for the committee appointed at the annual meeting to consider the petition from the General Censors' meeting, that the various Boards of Censors might be allowed to hold special meetings at their pleasure, presented the following report, which was accepted by the Council:—

The committee find in the Revised Statutes of Mas-

sachusetts, Part I., Chap. XXII., Sect. 3, the following:—

"The meetings of the Censors shall be held in those districts respectively, in such places and at such stated periods as the Councilors of the Society may direct."

Also, in the By-laws of the Society, 1881, XX., line 8:—

"The Censors shall meet as hereinafter designated, or at such times as the Councilors may direct."

Also in the Digest of the Acts of the Commonwealth relating to the Massachusetts Medical Society, XIX.:—

"The Censors elected by the District Societies for the purpose of examining candidates shall, at least three of them, be convened in Boston on the Thursday next preceding the annual meeting of the general Society, and at such other times and places as the By-laws shall direct."

The committee find no prohibition of special meetings other than those designated, but such meetings would be manifestly informal or illegal, as authority is granted to no one to call such meetings, and the chairman of a Board of Censors who should summon the Board at other times than those designated would be in the position of a speaker of the House who should, on his own responsibility, attempt to convene the House at an irregular time. This, however, does not prevent special meetings of the individual Censors to consult as often as they may deem fitting, such meetings being analogous to conferences or meetings of committees, and not official, or for the transaction of official business.

The committee further do not find that it is advisable to ask the Councilors to appoint other times for the stated meetings than those already specified; for in By-law XX., lines 25-27, it is expressly stated as follows:—

"Any meeting of Censors, whether a quorum be present or not, may be continued by adjournment to such time, and place within the district, as may be determined upon by the Censors present."

If, therefore, the stated meetings as prescribed are insufficient in number, or occur at such times as may not be for the best interest of the District Society, it is within the power of the Censors of said Society to adjourn to such a time and as frequently as they may deem necessary. Meetings at irregular times, to accommodate individuals, are liable to cause confusion and are not advisable.

Farther legislation on the subject seems, therefore, unnecessary.

After various matters of incidental business the meeting adjourned.

Recent Literature.

Du Diagnostic de l'Ectopie Rénale. Par le DR. FRÉDÉRIC BEVRET, Ancien Interne Provisoire des Hôpitaux de Paris. (Publications du Progrès Médical.) Paris. Aux Bureaux du Progrès Médical, 6 Rue des Écoles. A. Delahaye and E. Lecronier, Éditeurs, Place de l'École de Médecine. 94 pages.

This little book considers the movable kidney from the point of diagnosis alone, and chiefly the differential diagnosis. It contains many, and is chiefly made up of, cases in which the symptoms caused by a displaced kidney have led to an erroneous diagnosis.

Medical and Surgical Journal.

THURSDAY, OCTOBER 18, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

THE DEDICATION OF THE NEW HARVARD MEDICAL SCHOOL.

SAID President Everett on November 4, 1846, in his address at the dedication of the then new medical college on North Grove Street: "The occasion which has called us together is certainly one deserving the public notice of the academic authorities. It arises from the growth of this department of the University to such a degree as to require the abandonment of the edifice which thirty years ago was erected not only for the immediate accommodation of the School, but with due reference to its prospective increase. Such a circumstance affords sufficient evidence of the skill and success with which this branch of the University is administered. It adds the strongest confirmation of that which is apparent from other indications not less satisfactory, that our Medical School has sustained its reputation under the competition of rival institutions and the steady elevation of the standard of professional merit throughout the country."

How little did President Everett foresee that at the end of little more than thirty years his words would be equally applicable to the dedication of another new building; the growth of this department of the University requiring an addition to that edifice which he assisted in dedicating "with due reference to its prospective increase"! No attempt was made either in the address of the President or in the introductory lecture of Professor Hayward, which followed, to forecast the future. The nearest approach to anything like prophecy occurred in the following sentence: "The greater the number of individuals whose perceptive powers have been awakened and guided by sound studies and wise discipline, the greater the probability that some sharpened glance will penetrate the yet undiscovered mysteries of nature." How much has been accomplished since that time in penetrating the mysteries of nature is shown by the retrospect of Dr. Holmes.

One noticeable similarity between the addresses of 1846 and those of the present day is the equal inability to-day to foresee the time to come when the newly dedicated building will be abandoned for one better fitted to the necessities of a future day.

We feel sure our readers will all be grateful to Dr. Holmes for his manly words in regard to the study of anatomy, and we hope his statements will have the weight that belongs to the words of one who speaks from knowledge:—

"In face of the idle and baseless stories which have been circulated, I will say, as if from the chair which I no longer occupy, that the conduct of the difficult, delicate, and all-important branch committed to the care of a succession of admirable Demonstrators, as I have known it through more than the third of a century, has been discreet, humane, faithful, unwearying in diligence; an honor to them and to the classes they have instructed in many of their most important duties."

One change is particularly noticeable to one who looks back to the previous ceremony which we have mentioned. The JOURNAL of that day contented itself with a bare mention of the two addresses, leaving their publication to an entirely separate sheet, deeming that its duty led it to respect the rights of a committee of the students to control the publication of such addresses.

THE WALTHAMSTOW MURDERS IN ENGLAND. CONVICTION OF AN INSANE CRIMINAL.

A RECENT trial in England illustrates the statement made by Maudsley, nearly ten years ago, that the medical jurisprudence of insanity is not so consistent with sound law and with the conclusions of medical science in that country as in the United States.

A young man, William Gouldstone, of sober, industrious habits, five years married, who had always been uniformly kind to those dependent upon him, came home from his work, drowned three of his children in fourteen inches of water, and battered in the skulls of his infant twins, as they lay on their mother's breast. He then said to a neighbor, "I am a happy man." To his wife he remarked, "I have killed all your children, now you will be single again, and I shall be hanged." To the police his statement was, "When I took my money last week, I thought of buying a revolver with it, but I altered my mind, as I thought it would make too much noise. I had a hard job with the two biggest. I thought it was too hot to have five kids in about three years and a half, and I thought I would put a stop to it." He made no attempt at concealment or escape. He had been employed at regular work, with good wages, was doing well, and had no misfortune or misconduct to think of, and no wrong had been done him. His only motive for the act was to translate his children to heaven, and to spare them the trials and sorrows of a troublesome world. His fellow workmen had noticed his mental depression, and his wife had perhaps suggested the idea of killing his children to his morbid fancy by once saying in his hearing that she wished the twins, lately born, dead.

The physician to the house of detention, where Gouldstone was confined previous to his trial, thought him insane, but was not called upon to testify. Dr. Savage, an accomplished alienist of London, after an examination of the prisoner *lasting from a quarter to a half of an hour*, gave evidence that he could not testify to his insanity from his own examination, or certify him as a lunatic, and that the accused knew that he was committing murder. From letters to the *Times* by

Dr. Savage, and by a jurymen on the trial, it appears that Dr. Savage's testimony was thought by the jury to be to the effect that Gouldstone was responsible, whereas, in his letter, Dr. Savage calls it "a typical case of insanity," and complains that he was not allowed to say that the man was irresponsible, because the judge ruled that to be a question for the jury and not for a medical expert. He and Dr. Sunderland apparently wished to express an opinion that Gouldstone was irresponsible, and seemed to be surprised that they were not so understood. The judge charged the jury that if the deed had been done with deliberation and a knowledge of the quality of the act and its consequences, the man was responsible. The jury found a verdict of guilty, after being out fifteen minutes, and the evidently insane man was sentenced to be hanged. A respite has been granted, however, for a fuller investigation of the case.

Whether the medical witnesses were not allowed time enough to make a proper examination, and were not permitted to give a direct opinion as to the murderer's insanity, or the judge and jury considered deliberation and a knowledge of the nature and consequences of an act to indicate responsibility, a bare statement of the facts is sufficient to show that there has been so evident a miscarriage of justice that there can be no real doubt that the man will be sent to an insane asylum rather than be hanged. No other result can come of a careful consideration of so clear a case of insanity in an enlightened community.

In two similar cases, in this State, a man who murdered his mother-in-law, and a woman who killed her child, both with deliberation and a knowledge of the nature and consequences of the act, were recently sent to insane asylums, the grand jury failing to find indictments, upon the evidence of a single competent medical man that the parties were insane. A man who murdered his wife at night, with most carefully prepared plans, was sent to an asylum for life, upon the evidence of two competent physicians that he was suffering from a form of insanity, under the influence of which he would be likely to commit such a crime, although he knew the nature and consequences of the act so well that he tried to conceal it and escape, and although there was nothing in the circumstances of the deed itself to indicate insanity. Two others, quite like Gouldstone, at the beginning of the trial, were declared by the medical witnesses to be too insane to make the plea of "guilty or not guilty" understandingly, and were sent to the insane asylum without even the formality of a trial.

If we felt disposed we might make comments of an *ex cathedra* character, with regard to Gouldstone's trial, similar to those with which we were favored by our friends across the ocean in their discussion of the Guiteau case.

A FRENCH SURGEON'S IMPRESSIONS OF THE UNITED STATES.

IMPRESSIONS of a Trip to North America is the title of a sort of *feuilleton* which has been running through numbers of the *Lyon Médical* for a good many weeks. We recognize in the writer M. Poncet, the former sympathetic assistant of Monsieur Ollier at the Surgical Clinic at Lyons. He evidently came to the United States in as unprejudiced a frame of mind as a Frenchman ever visits a foreign country, and exhibits a candid desire to record his impressions, whether favorable or unfavorable, fairly and impartially, as they were received.

Although it is becoming more the fashion than formerly for the educated classes in France to study other languages than their own, it is still true that Frenchmen travel less than either Germans, Englishmen, or Americans, and when they do travel they carry ever closely present in their thoughts the home standard and the home ways. On the other hand, we Americans have grown sufficiently broad to read with perfect equanimity impressions, and even criticisms, of our habits and customs, provided they are free from malice, or do not come from the pen of one of our own novelists, though the line of toleration being drawn at the native writer shows that we have not yet quite outgrown the narrow spirit which led to the persecution of Cooper by a former generation.

M. Poncet, however, being a foreigner, we shall venture to offer our readers whatever profit is to be derived from seeing ourselves as others see us, and the more readily as it is easy to perceive that, even where exaggerated in details, these impressions offer a by no means untruthful sketch in French charcoal of a country viewed somewhat hastily and superficially through French spectacles.

The writer, as professionally bound, visited the medical centres, the schools and hospitals, and made the acquaintance of medical men, and speaks in handsome terms of approbation of much that he saw. The Boston City Hospital and the Massachusetts General Hospital met with especial approval in his eyes, and his visit to the latter inspires an account of the ether controversy. Boston is called the literary and artistic capital of North America, and the justness of its claim to the title of the Athens of the United States is conceded. A more delicate compliment to our good city is implied where, upon the return home, Lyons is styled the Boston of France. The ambulance service of our hospitals, especially as exhibited at the Chambers Street branch of the New York Hospital, is cordially appreciated.

The writer, however, by no means confines his observations to strictly professional subjects, and the keen eyes of the sometimes too quick-witted Gaul note many things in sociology and anthropology as he travels from place to place and sojourns in hotels. He is struck with the capacity shown by the Anglo-Saxon race for assimilating all others, and by the fact that in the second generation English becomes the universal language. It seems to him, too, that certain

— A M. Sebas informs the French Academy of Sciences that he has discovered a method of causing the alcoholic fermentation to take place in the pulp of melons by adding sulphuric acid. Thirty kilogrammes of pulp will yield five litres of alcohol.

physical characteristics, whether by the mixture of races or under the influence of other factors more or less appreciable, are undergoing rapid modifications. He is struck by a certain similarity of conformation between the women of the "New World" and those of "blonde Albion;" both are deficient in "*pectus*," the mammary glands are but little developed, or there is at least a want of harmony between the size of those organs and the general figure. The upper part of the body, apart from the head, which is often very expressive, sometimes extremely beautiful, is disappointing in volume. The pelvis and the lower limbs, on the other hand, he finds well developed. This disproportion frequently struck the writer at the hospitals. He concludes that the German transplanted to the United States will become less productive, and in this respect more and more like the native American.

It is in his sociological impressions that M. Poncet becomes most interesting and instructive. The apparently small value set upon domestic life, and the mode of preparing and partaking of food and drink prevalent among the inhabitants of the United States, as he saw us, are set down with a robust frankness which the writer evidently thinks scarcely adequate to depicting the reality. These did not harmonize themselves with a taste formed upon the conservative and moderate *vie de Province*, upon the *cuisine Française*, and *vin de Bordeaux*.

What the American woman lacks in *pectus* she makes up in intellectual culture, which is superior to that of the man. Not that her earlier education is better, but later in life, at her own fireside, she has more leisure to devote to study. The man lives but little at home; always more or less mixed up in commercial or industrial undertakings, he is constantly pursuing the dollar, which is not caught whilst asleep; he is nothing if not "professional"; the artistic, the scientific, side of things escapes him almost entirely; one must win money, and that in large quantities and as rapidly as possible. Family life and the intimacy of the domestic interior are diminished by the taste for travel or, rather, the desire for change, and by the ease with which one establishes a domicile for weeks or months in a boarding-house or on a steamboat. When the day is over, and affairs are finished, the American enters his "habitation," but hastens to leave it as soon as possible to indulge his favorite taste. He has a strong love for really alcoholic drinks, but does not *dare*, that is the word, to make use of them even moderately before his wife and children. He has no objection to return home tipsy, but having drunk nothing in his own house the national *respectability* is preserved. Notwithstanding his boasted freedom he is the slave of prejudices and certain conventionalities from which one would suppose him to be free. He drinks iced water or milk at his meals, cocoa or sarsaparilla on a holiday, and then by a back door seeks a concealed corner of a bar-room where he pours down several little glasses of whiskey and brandy, accompanied again by big glasses of the all-pervading iced water, which latter, it is conceded, has

its advantages during the extreme heats of summer. The writer thinks that the consumption of ice in the United States must be something frightful, and he understood the amount of dyspepsia and gastro-enteritis attributable to it was very great. He permits himself to hope that less iced water is drunk in winter. The same extreme summer heats cause doors and windows to be left open recklessly if not with entire impunity, the expression "*courant d'air*" finding no place in the language.

If there is any truth in the proverb, "Tell me what you eat, and I will tell you what you are," it is amply illustrated in the New World. The American does not eat, he simply fills himself; his sole desire is to satisfy hunger, and if he can secure quantity quality is of little importance; hence one frequently sees him ingest a lot of food standing up, or scarcely seated, at a counter. There are fixed hours between which meals may be had, and food must be taken at those times whether one be hungry or not. A despotic, all-powerful public opinion, which no one dares defy, decrees the hours for eating. The meals are always begun with a square block of rancid butter, having an odor of margarine. A pause of fifteen to twenty minutes gives time to attempt the digestion of this compound, and then you find yourself surrounded by a variety of little dishes which you expressed an intention to eat. It matters not that they become cold, for do you not see around you "des misses, des ladies, des gentlemen" eating watermelon with chicken, and currant jelly with cutlets and salad! Behind your chair is one negro who fans you, and another who puts ice in your glass. The writer apparently was not struck with the number of our religions, but it does not escape him that we have but one sauce, and that like glue, by which otherwise good meats are ruined. Our eggs have a queer, stale, animal flavor, which is supposed to result from the hens being fed upon meat that they may lay more. Corn is a favorite article of food, and though eaten in various ways is most often boiled on the cob. Three or four of these cylinders are not too much for a lover of this cereal, who will gnaw off the grains with his teeth, and presently leave nothing but "*la carcasse*."

There are, it is true, several good restaurants in New York where one is served more or less *à la Française*, but the prices are prohibitory. It is surprising to the writer that there are no good hotels or restaurants, but he can only explain it on the ground that the Yankee is enchanted with whatever he finds in his own country, and has as limited aspirations in matters of the table as in the fine arts; to give him anything better would be lost trouble; he would not avail himself of it.

The sum total of all this is that in America one lives very badly, and the writer can scarcely believe that it is likely to be selected as a country in which to travel for pleasure. The inhabitant of this country has a good opinion of himself and of his nationality, which surpasses all that one can imagine, and leaves the *chauvinisme* of the French, and the arrogance of the English, far in the background. A view

of the situation which leads us to suspect that the peculiar American humor escaped M. Poncet's comprehension altogether.

After first reading these impressions of M. Poncet, of which the above are examples, we experienced a feeling akin to that caused by seeing Sardou's "Oncle Sam" when first brought out in Paris, and which phrased itself in "a monstrous caricature;" but second thoughts will not permit one to deny that there is a large substratum of truth upon which to base the confidences concerning his trials which the writer makes to his fellow-townsmen, nor is the view of our semi-public hotel and steamboat life a very distorted one, especially when taken by a Frenchman on a summer trip and without his *eau rouge* and *petit pain*.

We bear M. Poncet no malice, and will promise in any case to avoid the little glasses of whiskey and brandy followed by the big tumblers of iced water at the back door of the bar-room, and moreover to sit at home and sip Bordeaux, if he will only win the Academy's prize for devising the destruction of the phylloxera.

MEDICAL NOTES.

— Recent experiments indicate that dogs can eat and digest a quantity of meat equal in weight to from one tenth to one sixteenth of the body. Cold coffee increases very much the appetite and digestive capacity, and after taking it nearly double the quantity of meat may be consumed.

— The French papers report a centenarian named Marie Durand as having been born March 16, 1761; married to Claude Gerard in 1783; a widow for ninety-six years; and still alive at the ripe age of one hundred and twenty-two years.

— Dr. Lucy M. Hall, of the Reformatory Prison for Women at Sherburne, contributes to the October number of the *Journal of Inebriety* an interesting paper on the causes and results of inebriety in women. She has used the opportunities offered by her position to study the conditions under which women of the classes with which she is dealing yield to temptation, either subjective or objective, and become drunkards; and also the action of alcohol upon the organism and the resultant psychical and physical disturbances. She believes intemperance to be greatly on the increase among the female mill-operatives at our large manufacturing centres. Her experience leads her, we are very glad to note, to strongly advocate prolonged periods of control and surveillance, "not penal nor unnecessarily disgraceful, but absolute, without limit, and modified only by positive and continued evidence of reform in the sufferers. In this way only can the degree of usefulness of which they are capable be conserved and their impending ruin averted.

"Prevent those influences which lead to inebriety when possible; when not possible, prevent the further self-ruin of the inebriate by wise, humane, but absolute and unremitting control and protection."

— Another case of attempting to blackmail her medical attendant by a woman on a charge of adul-

tery has been before the courts in England, and again it serves as a text for editorial warning against attending any woman without the presence of a third person unless very sure of the character of the patient, and being sure of very few.

NEW YORK.

— At a meeting of the Society of Medical Jurisprudence and State Medicine, held October 10th, Dr. N. E. Brill read an elaborate report of the recent progress in medico-legal science in America and Europe. It was pointed out in the paper that both England and the United States were much behind continental countries in this department, and the fact was generally admitted in the discussion which followed; in the course of which Mr. Max Eller explained the great pains that were taken in German universities to arouse interest in the subject.

— The Maternity Emergency Hospital in East Twenty-sixth Street, near Bellevue Hospital, has been temporarily closed, by order of Dr. Wm. T. Lush, for thorough disinfection and the repair of defective plumbing. There has been no epidemic of puerperal fever, but two of the lying-in patients having recently suffered from malaria, it was deemed advisable to vacate the premises for a time by way of precaution.

— A case has come up in the courts of violation of the new law known as the Tenement-house Act, which forbids the manufacture of cigars in the city of New York in any section or apartment of a tenement-house in which the manufacturer lives and does household work (with the exception of the store or ground floor), and Judge Dittenhoefer, the counsel for the prisoner, proposes to contest the constitutionality of the act. "By its terms," he said, "it purports to have been enacted to promote public health. If the act really is in the interest of the public health, it is undoubtedly constitutional, for the Legislature has the inherent power to deprive any citizen of the enjoyment of his property if its use is detrimental to the public health. But if that be a mere pretext, and the law operates to protect the health of the individual only, assuming that the manufacture of cigars is unhealthy, the Legislature had no power to pass this law, and it is evident from the law itself that the Legislature must have concluded that the manufacture of cigars is not injurious to the public health, otherwise it would not have permitted such manufacture on the ground floors of tenement-houses."

— The "Old Code" men have been making special efforts to secure the defeat of the proposed amendments to the Constitution and By-laws of the Academy of Medicine, and on the 15th a meeting was held for the purpose of aiding in this, in answer to the following call sent out to the Fellows of the Academy:—

"It is thought to be of the greatest importance to the welfare of the Academy of Medicine that the proposed amendments to its Constitution and By-laws be defeated. Will you therefore meet some of the friends of the Academy who are opposed to the passage of these amendments, and who desire to put an end to the discussion of codes of ethics in that body? The

intended conference will be held at the Mott Memorial Hall, 64 Madison Avenue, on Monday, October 15th, at 8 P. M." (Signed) Alouzo Clark, T. M. Markoe, Abram Dubois, John T. Metcalfe, H. D. Nicoll.

— Dr. Frederick D. Lente died at Cold Spring, on the Hudson, in the sixtieth year of his age, on the 11th of October, of cerebro-spinal meningitis. He was born in Newbern, North Carolina, and was a graduate of both the University of that State and the University Medical College of New York. He studied for a time under Dr. Alfred C. Post, and afterwards served for two years under Dr. Valentine Mott, on the house staff of the old New York Hospital. In 1851 he was appointed surgeon to the West Point Foundry at Cold Spring, where he remained until 1871, in the meanwhile building up a very extensive family and consulting practice on both sides of the Hudson. He then came to New York, and was appointed to the chair of Gynecology and Diseases of Children in the University Medical College; but, on account of ill-health, was obliged to return to the country in the following year. He remained at Cold Spring till 1875, when the condition of his health forced him to again make a change. He then began to practice at Palatka, Florida, in the winter, and at Saratoga Springs during the summer months; and this he continued up to the time of his last illness. Dr. Lente was an enthusiastic and industrious worker in the profession, and a large and original contributor to periodical medical literature. He was one of the founders of the American Academy of Medicine, and its first president. He was also an honored member of the American Neurological Association and of many other societies, and died universally beloved for his many genial qualities, as well as respected for his high scientific attainments and noble character.

— The body of Dr. Charles S. Blumenthal, a prominent homœopathic physician, lately deceased, has been taken to Washington, Penn., for cremation, in accordance with a special request that he left.

“KNOW DR. KNAPP!”

WE extract the following passage from the introductory lecture of a distinguished New York ophthalmologist as given in the *Medical Record* of October 6th:—

“Ten years ago I was consulted by a Boston physician for a serious ophthalmic difficulty. I advised him to stay in New York and have his eyes treated. He asked me, quite astonished, ‘Why, have n’t we as good physicians in Boston as you have in New York?’ I replied without feigned modesty, ‘No, sir, and you never will have; for talent, like merchandise, has a tendency to seek the best market.’ He understood, stayed, had his eyes cured, and soon afterward settled in New York himself.”

“The old philosophers,” says our lecturer farther on, “held it to be the highest maxim, ‘Know thyself.’” But the essence of the philosophy here inculcated appears, to our provincial comprehension, to be “Know Knapp.”

Miscellany.

THE HOT BATH IN ASPHYXIA.

THE *Australasian Medical Gazette* reproduces from the *Journal de Thérapeutique* a note on this subject as follows:—

A short time ago Dr. Goyard published the case of a still-born child which revived almost immediately after being put in a bath of 122° F., though for more than two hours he had tried in vain electricity, friction with hot cloths, and insufflation, to restore life. Hot baths of such a temperature are generally dangerous. From P. Bert's experiments it is well known that immersion in a bath of 122° F. for longer than a quarter of an hour is fatal, in consequence of the coagulation of the interfibrillar juices of the muscles, therefore caution is necessary. The still-born child should never remain longer in the bath than four or five minutes, and if there is no sign of respiration after three minutes, it may be considered dead. If left longer in rigor mortis will surely set in, and this the practitioner, even for appearance sake, ought to avoid; nor should the temperature, measured by the thermometer, ever exceed 122° F. The first respiration generally begins during the first and second minute, and after three or four minutes the child should be taken out. The reviving effect of the hot bath in Goyard's case is the more remarkable as he and his assistants had given up all hope, and believed the child already to be dead for some time. Hot water can always be had in confinements. Dr. Gustave le Bon believes in no other means of saving life of asphyxiated persons than application of heat and artificial respiration. Insufflation, he says, is worse than useless; it only drives the air in the stomach, which it distends, and thereby impedes respiration; or if it were possible by a tube to force air into the lungs and into air cells, the pressure of the air thus forced in would only compress the capillaries; even artificial respiration is useless if the blood is already coagulated. The success of the hot bath in cases of asphyxia of still-born children led to its trial in asphyxia from drowning, but without very marked results. In drowning two kinds of asphyxia occur; people who fall into the water may faint at once (syncope), whatever may be the cause of it, and the shock, the sudden cold, etc., may cause respiration to cease immediately, consequently the characteristic signs of suffocation by drowning are absent; such people may recover even if they have been under water for more than a quarter of an hour. Others try to breathe while submerged, and in those we always find the usual signs of suffocation, namely, congestion of the lungs, ecchymosis of pleura, etc., but especially clots of coagulated blood in the heart, in the larger vessels and their branches. These clots form three or four minutes after asphyxia begins, hence it is clear how vain all our efforts to restore life in such cases must be. Le Bon shows by his experiments that asphyxia from drowning takes place not only through coagulation, but also through the lowering of the temperature of the blood, which again is caused by the temperature of the water, as well as by the interruption of the respiration, which, as is well known, is the chief source of heat of the body. Even after prolonged cold bathing asphyxia never occurs, but the temperature of submerged animals sinks rapidly during their struggles for breath, and the same happens in other cases of asphyxia, that is, from carbonic acid. In a person taken out of the water ap-

parently dead, not only is the temperature of the body lowered, but it continues to fall still more, and death must be the natural result. It is therefore plain enough that the first step towards a rational treatment is the application of artificial heat. Hot cloths, however, soon lose their heat, hot bricks, etc., act only locally, but a hot bath of 122° F. will often prove successful if used with caution, and for no longer time than a few minutes. If one so hot is not at hand, water of a temperature from 97° to 100° F. will be sufficient to prevent the temperature from sinking below the normal, but it then becomes necessary to place the patient before an open fire, guarding nose and mouth against the direct heat of it. A temperature of from 90° to 100° F. can in this way easily be borne. The thermometer, showing the temperature of the body, should now guide us in our further treatment; it will decide when it is time to put the patient to bed, how long we may leave him in it or remove him again to the fire, and what distance from or near it will be the most useful for him.

BOSTON DISPENSARY.

The statistics of this institution for the year ending September 30, 1883, are as follows: The number of new patients treated at the central office is 14,382, classified as follows: Medical Department, men, 2330; women, 4161; children, 2058; total, 8549. Surgical Department, men, 1689; women, 411; children, 346; total, 2446. Dental Department, men, 268; women, 441; children, 580; total, 1289. Skin Department, men, 479; women, 267; children, 172; total, 918. Department for Diseases of the Nervous System, men, 51; women, 46; children, 9; total, 106. Department for Diseases of the Throat and Nose, men, 268; women, 361; children, 193; total, 822. Department for Diseases of the Eye, men, 39; women, 62; children, 53; total, 154. Department for Diseases of the Ear, men, 24; women, 37; children, 37; total, 98. The number of visits made by patients, old and new, at the central office, is 26,623, classified as follows:—

Medical, 14,037; surgical, 12,586; total, 26,623.

The number of new patients treated in the districts is 12,915, including 151 cases of midwifery, classified as follows: men, 2384; women, 4916; children, 5617; total, 12,915.

The results of treatment in the Districts are as follows:—

Discharged cured or relieved	11,794
Removed to hospitals	796
Died	311
Remaining under treatment	76

12,976

Under treatment at last annual report

61

12,915

The number of new patients treated in the central office and in the districts is

27,297

Number of cases of midwifery attended during the year

151

Number of cases of midwifery attended since July, 1858

4,018

Whole number of patients since October, 1796

841,712

Whole number of patients since July, 1856

722,909

Average daily attendance at the central office during the year

84

Surgeons: Thomas Waterman, M. D., Charles E. Inches, M. D., J. Foster Bush, M. D., Francis H. Williams, M. D.

WILLIAM H. H. HASTINGS, M. D., Superintendent.

LADIES' DRESSES.

COMMENTING on a letter from Dr. Horace Dobell in the *London Times* concerning the bad effects of the "braces system of suspension" for women's dress, in which he urges that the hips, and not the shoulders, are the best part of the human frame for the support of weight on the ground that braces restrict the elevation and antero-posterior expansion of the chest-movements, even more important, as the writer justly observes, to women than to men, the *British Medical Journal* agrees that there is much truth in these remarks. It trusts, however, "that the assertion that the system of suspension of the clothes from the shoulders is the outcome of the arguments used by 'dress reformers' against tight lacing will not be seized by the ladies as a statement in favor of continuing the use of stays. The evils referred to by Dr. Dobell doubtless are often produced by the use of braces, and especially when a heavy weight is suspended. This weight is often unnecessarily great in consequence of the looseness of ladies' clothing. If, instead of hanging a quantity of loose clothes round the legs, the garments covering these extremities were chiefly close-fitting, the weight of the clothing might be very much lessened, because when close to the body they preserve the warmth much better than when surrounding the legs loosely. The principle of dual garments might be carried on without altering the external appearance of female dress; for, with the use of warm, close-fitting drawers or trousers, the outer skirts might be made in the usual manner, but of much less thickness and weight. Many ladies now wear neither stays nor suspenders, and yet experience no difficulty in supporting their skirts, chiefly upon the hips."

We have long thought that, in their zeal against tight lacing, our "dress reformers" were doing society a disservice in decrying the moderate use of stays, and were likely to provide the profession with a crop of evils resulting from their contrivances quite as formidable as any hitherto traced to the abuse of corsets. The thoracic organs are quite as worthy of fair play as the abdominal.

ATTENUATION OF CHANCROUS VIRUS.

THE *Lancet*, commenting on M. Aubert's researches regarding the vitality of chancrous virus, says:—

"We have already drawn attention to the hypothesis that the principle of attenuation may play an important part in the explanation of some of the remarkable changes which diseases undergo, either under the influence of intentionally administered agents or from the action of quasi-accidental circumstances originating

within or without the organism. The notion of destroying or annihilating a disease can only be entertained side by side with the belief that the chief factor of a disease is some tangible entity. Absolute extermination can only be aimed at whilst the micro-parasites exist in the environment. When once the organism is attacked we must trust to attenuation. Chemically the distinction between destruction and attenuation, however great, may be regarded as one of degree. In destruction we may say there is a passage from the organic to the inorganic; whilst in attenuation the transition may be to a body which is equally vital, organic, and complex with the original poison, but possessing different physiological properties. One of the latest practical phases which this new development of the principle of attenuation has received comes from the observations and recommendations of M. Aubert. The author concludes from his experimental and clinical researches, that in the agency, heat, we possess an excellent means of attenuating the chancreous virus, and consequently of treating the simple chancre. He finds that a temperature a little above the normal body heat, of 37° C. to 38° C., destroys the virulence of the poison. It is necessary to combine elevation of the internal body-heat with that of local warmth, and practically to imitate what goes on in the organism affected with erysipelas when there is general fever and local heat. M. Aubert advises the employment of the hip-bath, made with water at a temperature of 40° C. to 42° C., and continued for several hours. Chancreous ulcers may thus have their virulence destroyed. This mode of treatment is considered to be the best for phagedænic ulceration, and for those subphimotic sores which ordinary dressings cannot touch. Similar treatment directed to specific buboes is said to convert them into simple abscesses. The value of the warm bath, hot fomentations, and the, at times, much derided poultice in the treatment of angry and virulent forms of inflammation has been long admitted. It is possible that a more scientific explanation than has hitherto been forthcoming of the *rationale* of these familiar remedies is afforded by the present notions of attenuation.

OPENING THE CHEST IN EMPYEMA.

IN a paper presented to the British Medical Association¹ Dr. Eddison tabulates forty cases of opening of the chest for empyema occurring in his own service and that of his colleagues at the Leeds Infirmary. He summarizes the conclusions which he thinks are supported by these cases in the following way:—

Children and young people do much better than adults. The duration of a case before operation has, on the whole, an unfavorable effect in proportion to its length. A very large amount of pus has a distinctly bad effect. Anæsthetics, ether at any rate, may be safely given provided the breathing and circulation are fairly good at the time. The particular point at which the chest is incised has not much importance. The contents should be allowed to escape slowly; the larger the quantity the more slowly should they be removed. The maintenance of free drainage is of the very highest importance; any accumulation of pus, owing to obstruction of the drainage tube or to any other cause, being followed by an increase of temperature and delay in the progress of the case. The use of antiseptics is worth the extra trouble; and al-

though cases may do admirably in which no antiseptics are used, yet on the whole patients do better and seem more comfortable when they are used both for operations and dressings. Simple cases of empyema—in which the lungs are themselves sound, and in which the other organs of the body are fairly healthy—are almost sure to do well, but it is not possible in any case to estimate its probable duration with any exactness. Cases in which fluid has reaccumulated repeatedly after having been drawn off, and especially when such fluid contains blood-cells, do badly, as a rule, though not always; in such cases it may be suspected that the lung itself is diseased, and probably tuberculous. No matter what complication is present, or what the probability of an ultimately unsatisfactory ending of the case may be, it is the duty of the attendant to incise the chest even if only for the sake of temporary relief from pain and distress.

CORROSIVE SUBLIMATE IN MIDWIFERY PRACTICE.

IN M. Tarnier's practice corrosive sublimate, in solution, has for some time been used as an antiseptic with great success (*Glasgow Medical Journal*, August, 1883, and *Journal de Thérap.*, February 15, 1883). Every one (nurse, students, etc.) who has to approach the patient has to wash the hands in the solution; this has not yet produced any indication of salivation in the attendants. When the patient is taken into the hospital she has a bath, if it is found convenient; the whole of the genital region is then carefully bathed with a 1:2000 solution of the sublimate; finally, the vaginal canal is thoroughly injected with the same solution (tepid), and a compress soaked in the same placed over the parts. During labor the injection is renewed about every three hours. After delivery is completed, another injection of the same kind is given, and the parts are carefully sponged with the solution. If labor has in all respects been normal and everything seems to be going on well, the parts are afterwards simply sponged externally with a 1:80 carbolic acid solution and covered with a compress soaked in the same.

If the labor has been completed by artificial aid, if there remain in the uterus portions of the membranes, if there is sloughing, or especially if the lochia turn fetid, the 1:2000 solution of sublimate is again used; four, five, or six times a day, a vaginal injection with the solution is practiced, the parts are sponged with it, and the napkins soaked in it.

Three hundred and fifty women have been treated in this way, and of this large number only one died. Her death was caused by peritonitis, and at the autopsy the remains of a former attack of the same disease were traceable.

Under the influence of the sublimate, the lochial discharge loses all trace of fœtor in one or two days, and the fever diminishes rapidly. Involution of the uterus seems unusually rapid; in many cases, when the patient was dismissed on the tenth or fifteenth day, the cervix uteri was unusually firm, and had almost completely regained its normal shape and consistence. No case of salivation or of anything approaching to mouth symptoms, was met with among these patients.

In three cases of puerperal fever intra-uterine injections of the sublimate solution were used with perfect success.

Deaths reported 2337 (no report from St. Louis): under five years of age, 783: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 567, consumption 325, diarrhoeal diseases 210, lung diseases 150, diphtheria and croup 148, typhoid fever 88, scarlet fever 49, malarial fevers 28, cerebro-spinal meningitis 12, whooping-cough 12, puerperal fever seven, measles six, erysipelas six. From *scarlet fever*, Chicago 10, New York eight, Boston six, Philadelphia, Brooklyn, and Buffalo five each, Pittsburg and Milwaukee three each, Baltimore two, Providence and New Bedford one each. From *malarial fevers*, New York 11, Brooklyn six, Charleston four, Chicago and Baltimore two each, Philadelphia, New Haven, and Nashville one each. From *cerebro-spinal meningitis*, New York six, Chicago three, Worcester, Salem, and Holyoke one each. From *whooping-cough*, New York, Brooklyn, and Pittsburg three each, Philadelphia, Chicago, and Cincinnati one each. From *measles*, New York five, Baltimore one. From *erysipelas*, New York three, Brooklyn, Chicago, and New Haven one each. From *small-pox*, Nashville one.

In 36 cities and towns of Massachusetts, with an estimated population of 1,065,243 (estimated population of the State 1,922,530), the total death-rate for the week was 18.68 against 20.08 and 17.62 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending September 23d, the death-rate was 19.6. Deaths reported 3235: diarrhoeal 267, acute diseases of the respiratory organs (London) 167,

scarlet fever 114, whooping-cough 68, fever 67, measles 43, diphtheria 35, small-pox (Birmingham seven, Sunderland and London two each, Liverpool one) 12. The death-rates ranged from 14.6 in Derby to 22 in Newcastle-on-Tyne; Leicester 15.3; London 17; Portsmouth 18.3; Nottingham 19.9; Sheffield 20.8; Birmingham 22; Manchester 23.2; Liverpool 26.4. In Edinburgh 16.4; Glasgow 23.3; Dublin 24.9.

For the week ending September 15th, in 168 German cities and towns, with an estimated population of 8,665,993, the death-rate was 19.8. Deaths reported 3934; under five years of age, 2141; consumption 512, diarrhoeal diseases 326, lung diseases 256, diphtheria and croup 176, whooping-cough 62, typhoid fever 54, scarlet fever 58, puerperal fever 34, measles and *rötheln* 31, typhus fever (Berlin one) one, small-pox (Neustadt-Magdeburg one) one. The death-rates ranged from 13.7 in Wiesbaden to 38.9 in Posen; Königsberg 28.3; Breslau 25.6; Munich 26; Dresden 25.2; Berlin 25.8; Leipzig 22.7; Hamburg 21.5; Cologne 22.4; Frankfurt a. M. 17.1; Strasburg 24.9.

For the week ending September 22d, in the Swiss towns, there were 18 deaths from consumption, diarrhoeal diseases 17, lung diseases 12, whooping-cough seven, typhoid fever four, scarlet fever one, erysipelas one, puerperal fever one. The death-rates were, at Geneva 12.3, Zurich 2, Basle 18.3; Berne 12.4.

The meteorological record for the week ending October 6th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

Date.	Barom-eter.	Thermom-eter.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM OCTOBER 5, 1883, TO OCTOBER 12, 1883.

HAMMOND, JOHN F., colonel and surgeon. Leave of absence on surgeon's certificate of disability granted April 2, 1883, extended six months on surgeon's certificate of disability. Paragraph 7, S. O. 231, A. G. O., October 8, 1883.

SWIFT, EBENEZER, lieutenant colonel and assistant medical purveyor. Under the provisions of Section 1 of the Act of Congress approved June 30, 1882, is, by operation of law, this day retired from active service, and will proceed to his home. Paragraph 4, S. O. 231, A. G. O., October 8, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING WEEK ENDING OCTOBER 13, 1883.

HILAND, THOMAS, surgeon, granted leave of absence for one year, with permission to leave the United States.

SIMON, WILLIAM J., surgeon, and CRAWFORD, M. H., passed assistant surgeon, ordered to report on November 1st for duty on board the U. S. S. Trenton.

DEATH. SURGEON-GENERAL CRANE.

BRIGADIER-GENERAL CHARLES H. CRANE, Surgeon-General, United States Army, died suddenly in Washington, on October 10th, in the fifty-eighth year of his age. For a few weeks he had complained of a severe cold, which especially irritated his throat; he continued to perform his official duties, however, until about two weeks previous to his death, when, in accordance with the advice of his physicians, he remained at home. Two days before his death his symptoms became alarming, and an unexpected hemorrhage was the immediate cause of death. Dr. Crane was born in Rhode Island in 1826, and was appointed to the Medical Department of the Army, from Massachusetts, in February, 1848. He was made full surgeon in May, 1861, and Assistant Surgeon-General on July 28, 1866, and Surgeon-General in August, 1882, on the retirement of his predecessor, Surgeon-General Barnes.

NINETEEN CASES OF URETHRAL STRICTURE TREATED BY INTERNAL URETHROTOMY, WITH REMARKS.

BY G. H. TILDEN, M. D., AND F. S. WATSON, M. D.

Of the nineteen cases of urethral stricture subjected to Otis's operation of internal urethrotomy, to the consideration of which we beg your attention this evening, thirteen have been treated by ourselves, and for the opportunity of reporting the remaining six we are indebted in two instances to the kindness of Dr. Morse, and in the other four to that of a member of the Carney Hospital staff.

In presenting this short series we wish to offer first an analysis of the cases, and subsequently state a few conclusions to which we have been led by our experience.

ANALYSIS OF CASES.

Causation. In all cases gonorrhœa.

Duration of Symptoms of Stricture. Average duration, six years. Longest duration, twenty years. Shortest duration, one month.

Age of Patients. Four cases aged respectively fifty, sixty-six, forty-five, forty-nine; all the rest were young men under forty.

Symptoms. Gleet was present in all cases except one, and the only symptom in three. Abnormal frequency of micturition in ten. Pain or uneasiness on micturition in eight. Neuralgic pains in back and legs in six. Changes in size or form of stream in ten. Muscular and mental fatigue in all.

Number, Size, Situation, and Character of Strictures. The strictures were all well organized. All anterior to four inches from meatus except one, which was situated at five and a half inches. The largest number of strictures in any one urethra was five. In four cases there were three strictures. In seven cases there were two strictures. In the rest there was one in each instance.

The calibre of the strictures varied in different cases from fourteen to thirty-one French scale. A detailed table follows:—

No. of Case.	Normal Calibre of Urethra.	No. and Situation of Strictures.	Their Calibre (French.)
1	34	At 1 inch, at 1½, at 3½.	26.
2	34	At ½ inch, at 1, at 3.	21, 21, 22.
3	34	At ½ inch, at 2½, at 3½.	23, 21, 24.
4	40	At ½ inch, at 3½.	31, 21.
5	31	At 2½ inches.	28.
6	32	At 3½ inches.	26.
7	31	At 2½ inches, at 3½.	21, 21.
8	31	At 3½ inches, at 5½.	15, 15.
9	34	At 3 inches.	14.
10	32	At ½ inch, at 3.	29, 29.
11	34	At ½ inch, at 2½, at 2½.	28, 21, 21.
12	30	At 3 inches.	25.
13	30	At 2½ inches, at 3.	21, 27.
14	30	At 2 inches, at 2½.	23, 24.
15	30	At 2½ inches.	18.
16	33	At 3 inches, at 3½.	25, 22.
17	34	Five strictures.	23.
18	33	At 3 inches.	30.
19	30	At 1 inch.	23.

Complications. In one case gonorrhœal rheumatism. In one case hypertrophied prostate. Examination showed no renal complication in the urine of any of these patients.

¹ Read before the Surgical Section of the Suffolk District Medical Society, October 13, 1883.

Preparatory treatment consisted in all cases of rest in bed, quinine, citrate of potash, or buchu, and a careful diet for from thirty-six to forty-eight hours preceding the operation.

Following the operation five of the nineteen cases had constitutional disturbance, consisting of one or more chills and a rise of temperature.

One of these cases had partial suppression of urine during thirty-six hours, several chills, and a high temperature; this was the only case which had a serious aspect.

In the other four cases the chill and fever occurred within thirty-six hours after the operation, and were not repeated.

Hæmorrhage. None of consequence occurred in any case. The average length of confinement to the hospital was six days. The longest period was fourteen days. The shortest two days.

Chordee. In four cases no chordee followed the operation; in all the others chordee was present to a greater or less extent.

Cessation of Gleet after the Operation. Gleet had been present for several years previous to the operation in most of the cases. In thirteen cases gleet ceased entirely after the operation. The average time of its persistence in these cases was thirty-two days. The longest lasted three months. The shortest lasted ten days. In the remaining six cases gleet was present in two at the end of ten weeks. Of the other four two were lost sight of, a third had no gleet at any time. A fourth case still had gleet at the end of five months.

CESSATION OF GLEET AFTER OPERATION.

No of Case.	Previous Duration of Gleet.	Cessation after Operation.
1	Five years.	Six months.
2	Three years.	Twelve months.
3	Five months.	Nine months.
4	One year.	Four months.
5	Two years.	Six months.
6	Ten months.	Four months.
7	Twelve years.	Four months.
8	Uncertain.	Three months.
9	Uncertain.	Fourteen months.
10	Three years.	Ten days.
11	One year.	Fourteen days.
12	Five years.	Eighteen days.
13	Uncertain.	Ten days; recurrence at end of nine months, with recontracted meatus.
14	Uncertain.	Ten weeks after operation still has gleet.
15	Four years.	Ten weeks after operation still has gleet.
16	Nine months.	Five months after operation still has gleet.
17	Ten months.	Lost sight of case.
18	Uncertain.	Lost sight of case.
19	No gleet at any time.	

Recontractions. In one case there has been a recontraction at the end of five months. In none of the others was any present at the last examinations. The time which has elapsed since operation is too short, however, to enable us to state that a recontraction may not yet occur in some of the cases.

Neuralgic pains, frequent micturition, except in one case complicated by hypertrophied prostate, and general malaise have in all instances disappeared within the first few days following the operation, and have not returned.

The conditions following internal urethrotomy, when done by Otis's method, are, in an ordinary case, slight hæmorrhage, some pain during micturition, which varies in amount in different cases, and a moderate evening rise in temperature for a day or two. Rest in bed

is necessary for a few days, and confinement to the house is advisable for about a week, at the end of which time the only symptoms remaining are more or less chordee and urethral discharge. All other symptoms which may have been due to the presence of urethral stricture, such as nocturnal and diurnal frequency of micturition and reflex symptoms of a nervous character, disappear. There is quick relief also from the fatigued condition both of mind and body which is so frequent an attendant upon urethral stricture, and in not a few instances a well-marked and rapid increase of weight manifests itself after the operation. The subsequent passage of sounds is oftentimes painful, but much gratuitous suffering may be spared to the patient if each passage of sounds is begun with the introduction of an instrument several sizes smaller than the full size to which the strictures have been divided. The use of conical steel sounds is required after the operation in order that the cut surfaces of the incised wound of the urethra may not unite, but may heal over from the edges, thus adding to the calibre of the urethra at the point of incision double the depth of the incision. By reason of the fact that in this operation the incisions are made anterior to the membranous portion of the canal, it is never necessary, except immediately after the operation, to pass the sounds beyond this point, and always inadvisable, as the repeated passage of instruments through the prostatic urethra exposes the patient to the risks of epididymitis and prostatitis. They should as a rule be introduced every other day, and the length of time for which this should be done of course varies in each case. When the incisions have thoroughly healed, a fact indicated by the absence of blood upon the sound and by the cessation of pain due to its introduction, if the strictures have been completely divided it is no longer necessary to subject the patient to this annoyance.

The operation of internal urethrotomy cures gleet in successful cases by removing stricture, which is the cause of gleet, and in this way places the urethra in the best state to recover from its chronic inflamed condition. Very often gleet will cease spontaneously after the removal of the stricture by which it is kept up, but sometimes other treatment is required either to hasten the progress of cure or even to bring it about at all. It should not be forgotten that there are other conditions besides stricture which may sustain a gleety discharge from the urethra. Areas of inflammation behind the sphincter muscles of the urethra, implication of its lacunæ and follicles, irritating conditions of the urine, and debility or lack of reparative power on the part of the patient, may all of them perpetuate gleet.

Another cause for the persistence of a urethral discharge, and one which is easily overlooked, is too much and too long continued meddling with the urethra by means of injections and the introduction of instruments. In many cases, however, the urethral discharge will cease spontaneously or with a little assistance after the healing of the wounds.

The passage of full-sized sounds after the operation serves another purpose than that of insuring the calibre of the urethra, it being also good treatment for the granular condition of the urethral mucous membrane, which exists behind and between strictures, and from which comes the gleety discharge. By reason of this it is sometimes advisable to continue their use after the wounds due to the operation have healed.

Other methods of treatment are general and localized injections and topical applications, preferably of a mild solution of AgNO_3 , to the inflamed areas of mucous membrane. General hygiene is of great importance, and preparations of iron are often useful. Copaiba, cubebs, and sandal-wood oil are sometimes of assistance, sometimes not. Their beneficial effect is soon manifest if they are of service in any particular case, otherwise they should be discontinued. Very essential are abstinence from alcohol and sexual excitement. Subsequent treatment should be continued until all mucous shreds disappear from the urine, for these are significant of areas of potential inflammation which, by reason of causes ordinarily inefficient, may at any time become actual.

The portion of the canal which shows the most marked tendency to contract after division is the meatus, and it is often extremely difficult to prevent this. The best method of obviating this tendency is to use a sharp knife, and to cut the orifice to as large a size as possible without producing hypospadias. A bit of lint smeared with carbolized vaseline should be kept in the wound of the meatus, being removed during micturition. The pain caused by micturition after the operation may be mitigated by immersing the penis in hot water during the act.

The dangers to life from internal urethrotomy are,—

- (1.) Hæmorrhage.
- (2.) Suppression of urine.
- (3.) Pyæmia.

(1.) *Hæmorrhage.* This is rarely of any consequence, and if detected is always to be controlled by pressure with ease if the incisions are anterior to the membranous urethra. Hence the necessity for limiting the use of the urethrotome to strictures which are anterior to this, and the reason for keeping the patient in bed and under observation for some days. Pressure may be applied to the fixed portion of the urethra in two ways, either by the application of a T bandage made of rubber and properly padded, which is fastened to a belt around the waist, or by a crutch, the cross-piece of which, well padded, is placed in the perinæum, while the other end rests against the foot-board of the bed. The patient straddles and bears down upon this, exerting in this way pressure upon the deeper portion of the urethra. If the bleeding comes from the pendulous portion of the canal a simple bandage, with side splints, around the penis is sufficient, or the penis may be compressed between the abdomen and the T bandage mentioned above. The introduction and retention for a short time of a full-sized sound is sometimes effectual in arresting slight oozing of blood from the canal.

(2.) *Suppression of Urine.* To be looked for only in such cases as are complicated by renal disease. The urine of every patient should be examined before operating so that one's eyes may be opened to danger, and the possibility of its occurrence be taken into account. If casts and albumen be present in the urine the diseased condition of the kidneys is obvious enough, but pyelitis, which is the common source of danger in operations upon the urethra, is sometimes very obscure and difficult of detection, being often complicated and masked by vesical disease.

Prophylaxis, such as it is, consists in preparing the patient for the operation by rest, sedatives, quinine, and diuretics.

Actual Treatment. The skin and intestines should be made to supply the place of the kidneys for the time being so far as possible. This means hot baths, and pilocarpine, and hydrogogue cathartics. This direction of treatment was well indicated in one of our own cases where during the time, thirty-six hours, in which there was suppression of urine, there was copious and spontaneous diarrhoea, which ceased as soon as the kidneys resumed their function. Unfortunately the above drugs besides their specific action have a very depressing effect, and this fact should not be forgotten. Counter-irritants over the kidneys are supposed to be of use in relieving the congested condition of those organs which very likely exists during suspension of their functional activity, and stimulants should be given in order to support the patient.

(3.) *Pyæmia* is a question of hospital influence and cleanliness of instruments. The urethrotome is an instrument very difficult to clean and keep clean. The best method of cleaning it is to boil it in water after each operation. If the urine is foul and ammoniacal by reason of cystitis antiseptic injections are of use.

The unpleasant complications of this operation which are not dangerous to life are,—

- (1.) Urethral chill and fever.
- (2.) Urethritis.
- (3.) Chordee and curvature of the penis.
- (4.) Periuethral abscess.

(1.) *Urethral Chill and Fever.* This chill is not very uncommon. It is usually single, and is a source of annoyance rather than of danger. Coming on after one of the first acts of micturition, generally within thirty-six hours of the operation, it is followed by a considerable rise in temperature as high as 103° F. to 104° F. This febrile condition lasts a few hours and gradually subsides, with profuse sweating, and there is no repetition of the attack.

Prophylaxis consists in rest in bed before the operation and the administration of diuretics and quinine.

Actual Treatment. During chill, heat and stimulants. For the febrile condition acouite is the best drug, combined with morphia if a sedative is required.

(2.) *Urethritis.* This is to be avoided by reducing any existing urethral discharge to a minimum before operating. As little violence as possible should be done to the urethra in operating, which means employing a sharp knife, not using the instrument as a divulsor, and making as few cuts as possible. The subsequent application of cold, in the shape of a cold water coil around the penis, is useful in preventing both bleeding and urethritis. The latter is to be treated by the application of hot water, and if the urethritis is septic in character, by the retrograde injection of some antiseptic wash, or by the introduction and retention in the urethra of iodoform bougies. Of course, during the existence of urethritis instruments should not be passed into the urethra, and acute inflammation of the canal after the operation is apt to destroy the chances of good to be derived from the latter.

(3.) *Chordee or Curvature of the Penis.* A certain amount of chordee is present in almost every case. It begins on the fourth or fifth day and lasts from two to three weeks, being a source of annoyance to the patient. It corresponds in duration and severity to the urethritis present, and is to be avoided by keeping the latter at a minimum.

(4.) *Periuethral Abscess.* An uncommon accident,

of which we have had no experience. Bevan, of Baltimore, reports four instances in a series of two hundred cases of this operation. It should be treated on general surgical principles.

In comparing Otis's operation with other methods of treatment for urethral stricture, the following remarks suggest themselves:—

Divulsion is undoubtedly a safe operation and is temporarily very effective, but it is open to adverse criticism. It is a rough and indiscriminating application of force which does not recognize the individuality of the urethra. That one urethra differs from another in calibre, and that the average calibre of the urethra is larger than the largest-sized divulsor which is in ordinary use are already demonstrated facts, and by reason of these facts it follows that many strictures will remain incompletely divulsed, and therefore inadequately treated by this operation. The wound, also, made by the divulsor, is a tear, the extent and direction of which are entirely out of the control of the operator, being probably determined more by the size and physical peculiarities of the stricture than by any other factor. The operation is much more efficacious in strictures of small calibre than in those of large size. Such a lacerated wound of the urethral mucous membrane, in cases of small stricture, is likely to be transverse as well as longitudinal, and to result eventually in that for which it is but a temporary remedy, namely, stricture of the canal. After divulsion it is as necessary for the patient to introduce an instrument for an indefinite period of time, as after treatment by gradual dilatation.

It is precisely these faults which are avoided in Otis's operation. In each case the work done is graduated exactly to the predetermined and individual size of the urethra, and a longitudinal incision is made through the stricture which has been put on the stretch in order that it may be more completely divided. It has been clearly demonstrated by Reybard, who was the first to use a dilating urethrotome, that longitudinal incisions in the urethra do not of themselves result in stricture of the canal.

It is interesting in this connection to note an extract from the report of the committee who awarded the prix d'Argenteuil to the treatise of Reybard upon Urethral Strictures, Paris, 1853. "M. Reybard has been led to adopt this method of operation by the study upon animals of the method of cicatrization of longitudinal wounds of the urethra. He has established the fact that such wounds, when prevented from reuniting, give rise to the formation of a cicatrix,—smooth, thin, and non-retractile,—which, in adding itself to the walls of the urethra, augments its calibre. The importance of this experimental fact has obliged your committee to neglect nothing which was necessary to prove its truth; it has therefore repeated the experiments necessary to demonstrate it."

Two dogs, whose urethras had been subjected to longitudinal incisions, were killed at the end of three and four months. The results of the examination of the parts which had been subjected to operation are as follows: "At the site of operation, a smooth, white cicatrix, two and a half centimetres long, one centimetre wide, and resulting from the separate cicatrization of the two surfaces of the wound. The urethra presented at this point a notable enlargement."

In addition to the above, confirmatory evidence in the same direction is afforded by the details of three

autopsies upon the human subject who had been subjected to internal urethrotomy, reported by M. Perrin.¹

First case, autopsy three years after operation: Stricture at the bulbous, and spongy junction; the stricture tissue was present at the autopsy, thirteen millimetres long. It was dense and fibrous. . . . The incision was plainly to be seen; the lips of the wound were still separated; they were thick, rounded, and fibrous, and slightly adherent to the subjacent tissues. The floor of the wound was occupied by a thin, supple tissue, perfectly distinct from the strict tissue.

In two other cases death occurred in twenty-three and forty days after operation. In the first there was no sign of inflammation or of induration. Under the microscope it was seen that mucous membrane had not been reproduced, and that the connective tissue covering the wound had no epithelial lining. In the second the surface of the wound was covered by mucous membrane.

The calibre of the urethra may be determined by the use of the urethrometer, or if this cannot be done on account of the small size or great number of the strictures present, a sufficiently accurate guide to the size of the canal is the relation which exists between it and the circumference of the penis, as first pointed out by Otis. The rule is this, that a penis of three inches in circumference possesses a urethra which, when fully distended, is of thirty millimetres calibre, and every increase of a quarter of an inch in the circumference indicates two millimetres increase in the size of the canal. It is surprising how constant this relation is, and in the many urethras which we have examined the variations from the rule have been that the calibre of the urethra was in reality larger than indicated by the circumference of the penis. Otis's instrument can only be used when the strictures to be cut have a calibre of fifteen millimetres or more, and if the contractions are smaller than this they may either be enlarged to this size by gradual or continuous dilatation, or immediately cut with Maisonneuve's instrument, Otis's instrument being used to complete the operation. The meatus has to be enlarged in almost every instance, it being nearly always much smaller than the rest of the canal. In 281 urethras examined with relation to this point by Otis and Weir, of New York, and Gross, of Philadelphia, the average size of the urethra was found to be 32.3 millimetres, that of the meatus 24.5 millimetres.

The chances of serious constitutional disturbance and danger to life in consequence of operations upon the urethra depend much more upon the condition of the patient than upon the method of operation. We cannot here do better than to quote the late Dr. T. B. Curtis upon this point, who, in an article upon *The Significance of Frequent Micturition*,² says, "A correct and complete diagnosis is of the highest importance for prognosis, since the success of all operations upon the bladder or urethra, whether for stone or for stricture, whatever procedure be employed, is strictly and almost exclusively dependent upon the degree to which the kidneys and pelves are implicated. Operations for stone or for stricture scarcely ever prove fatal unless the condition known as surgical kidney, consisting

in an inveterate suppurative pyelo-nephritis, be present. Nevertheless, however valuable a correct knowledge of the condition of the kidneys would be in such cases, we are generally forced to content ourselves with presumptions based upon the long duration of the primary disorder and the general condition of the patient. Among the most ominous signs of deep-seated mischief are polyuria, 'urinary dyspepsia,' and a liability to chills and fever, occurring with or without apparent cause." The above statement by Dr. Curtis places the matter in its true light, and it is unfortunate that the class of cases of which he speaks are very often those in which the necessity for some operative interference is imperative.

We have been at the pains to examine the surgical records of the Massachusetts General Hospital for the past ten years with reference to the frequency of constitutional disturbance during treatment for stricture, with the following results: In forty-seven cases of stricture treated by gradual dilatation there was one death, and constitutional trouble in 36.17 per cent., or in seventeen of the cases. In 113 cases treated by divulsion during the same period of time there were two deaths, and constitutional disturbance in 26.6 per cent., or in thirty cases. The average length of time for which these cases of divulsion were confined to the hospital was sixteen days. The number of cases treated in any other manner were too small to be worthy of notice. In the series of cases taken from the Massachusetts General Hospital records one point is worthy of notice, namely, that treatment by gradual dilatation was productive of constitutional disturbance in a larger proportion of cases than treatment by divulsion. Indeed, it is not rare to see cases recover without an unfavorable symptom after divulsion or internal urethrotomy which have previously suffered from severe general symptoms during treatment by gradual dilatation. It seems as if nature, irritated by impotent meddling, protested against such treatment until relieved by some more radical proceeding. This holds true more especially of small and numerous strictures of long standing where there is either retention or much difficulty in urination, and which are very likely complicated by renal disease. In such cases, where gradual dilatation produces attacks of chills and fever, repeated at each introduction of a bougie, this method of treatment should not be persisted in, but divulsion or urethrotomy should be done at once. There is nothing to be gained by delay, and the more radical methods of attack will, without increase of danger, which is always present in such cases, afford the most speedy remedy. An analogous relation holds between old-fashioned lithotripsy as done in several sittings, and Bigelow's operation, which affords immediate and permanent relief. In cases of stricture of large calibre uncomplicated by disease, and where there is no manifest dysuria, the converse of the above is probably true, and internal urethrotomy causes constitutional disturbance in a larger proportion of cases than would gradual dilatation. In these latter cases, however, the urethral chill and fever are not of serious import, and are to be regarded as an unpleasant incident rather than a serious drawback to an operation which offers fair promise of a permanent cure. The exact nature of this urethral chill is not known. It is possibly of purely nervous character, and is never accompanied by suppression of urine or any untoward consequences.

In one case to which Dr. C. B. Porter has kindly

¹ De la Valeur de l'Urethrot. Interne, Gazette des Hopitaux, June and July, 1865.

² Published in the Boston Medical and Surgical Journal of November 25, 1880.

allowed us to refer, where a slight operation upon the urethra was followed by an attack of this kind, the urine upon examination was found to contain large quantities of a well-defined and handsome specimen of bacillus. A catheter had been left in the bladder after the operation in the above case, but at all events, the concurrence of the attack of chill and fever, with the undoubted presence of micro-organisms in the urine, is suggestive.

Internal urethrotomy being unsuited to strictures situated posterior to the bulb by reason of uncontrollable hæmorrhage sometimes occurring and working back into the bladder, they are if of small size well treated by divulsion, although for such strictures external perineal urethrotomy is now being regarded with more favor than formerly. In the latter operation bleeding is under control, and the operation itself dangerous to life only in cases where any interference is dangerous. This operation owes its comparatively high death-rate to the fact that it has usually been done only in the desperate cases of tight stricture of long standing. Moreover, deep strictures, if of large calibre, are often particularly amenable to treatment by gradual dilatation. There is evidence, however, to show that many of them are spectres conjured up by the presence of anterior strictures of greater or less calibre, and thus their relative numerical importance becomes diminished. In every instance all anterior constrictions should be thoroughly removed before attention be given to the deeper ones, which may then vanish as if by magic. Our own limited experience also, as far as it goes, confirms the statement that by far the largest number of strictures are situated in the anterior portion of the urethra within four inches of the meatus; in other words, that deep strictures are comparatively uncommon. The cases which we have collected, so far as they go, illustrate how unnecessary it is to leave a catheter in the bladder after operation for stricture. Whether we would have had a smaller proportion of chills if we had done so is of course a mere matter of speculation, but the retention of a catheter in the urethra does not prevent the contact of urine with the wounded surfaces. If this be so it is worse than useless by the mechanical irritation of its presence, tending to cause urethritis and affording to micro-organisms a direct route to the bladder.

There is no one kind of treatment which is equally adapted to all cases, and a fair comparison of the different methods of treatment is only to be attained by taking into consideration the character of the cases as well as the method of operation. Like every other diseased condition stricture is more amenable to treatment of any sort when of recent formation, or generally speaking of large calibre, but in any case it is probable that complete division of the stricture tissue by means of the knife offers the best chance of a permanent cure. Sir Henry Thompson says in the Jacksonian prize essay upon Stricture, "I am disposed to think at present that a well-performed internal urethrotomy is more enduring in its results than any other operative procedure."

Treatment is modified in each instance by many attending circumstances, by the physical condition and idiosyncrasies of the patient, by his mental attitude towards the knife, and by the character, number, and situation of the strictures present.

We wish to be considered as reasonable advocates of internal urethrotomy as done by Otis's method, — an

operation worthy of more attention than has been given to it in Boston, an operation not proper in all cases, nor always successful, but one which, when rightly done in suitable cases, is the one of all others which, without danger to the patient, brings to him the most speedy relief and the best chance of a radical cure.

In concluding, we wish to express our thanks to the Sister Superior of the Carney Hospital for the excellent care and attention which have been bestowed upon our patients, and to Drs. Devine and Hall for their kind and intelligent management of the cases while under their care.

REPORT OF A CASE OF MURDER.¹

BY A. ELLIOT PAINE, M. D., MEDICAL EXAMINER.

ON the morning of September 26, 1879, I was called to Bridgewater to view the body of a man found dead in his house. I drove down, and, with one of the selectmen of the town, went to the house and found the dead body of Justin L. Gunn lying on the floor of a small bedroom, about eight by ten feet. The body was face downwards, with shirt and drawers on, in a mass of dried blood. There was no carpet on the floor, the only furniture in the room being an old-fashioned corded bed. There was one window on the side of the room, near the foot of the bed, and a door just at the head of the bed; there was another door at the opposite side of the room. The bed was in the corner of the room, so that it came near the door; the foot of the bed was drawn away from the wall about twelve inches; the bedclothes were thrown backwards, and the front part of the bed was depressed, showing that some one had lain there; the pillow and depressed portion were saturated with blood; the head-board and the walls, ceiling, and door, were spattered with blood. On investigation I learned that the deceased and his son had been living in the place a few months, carrying on a farm; that both had their sprees, and quarreled often. The son had remarked he would "fix the old man some day." The neighbors had last seen the murdered man on the evening of the 24th of September, about ten o'clock. He was then alone in the house. Nothing was seen of the father and son on the 25th, and it was supposed that they had gone away. On the morning of the 26th the neighbors noticed the cows had not been tied up, and were uneasy and noisy. The neighbors then looked around the premises; found the doors fastened. On looking into the bedroom window they saw the blood on the wall, and gave the alarm. In a sink in the room adjoining the bedroom, used as sitting and dining room, there was a small cabinet in which papers, etc., were kept. It had been broken open, and near it was a large screw-driver with blood on it. I did not examine the body at my first visit, but locked the house, and left it in charge of a neighbor, and sent a telegram to the district attorney asking for detectives. I also learned that the son was seen on his way to the railroad station (about three miles from the place) on the morning of the 25th of September.

In the afternoon of the day of the view, after getting authority to make an autopsy, I went to the house accompanied by the district attorney, and with the

¹ Read before the Massachusetts Medico-Legal Society, February 7, 1883.

assistance of Drs. Pratt and Sawyer I made a thorough examination.

On the pillow were a few small pieces of bone and brain substance. On the mattress, between the head-board and pillow, was a piece of bone about half an inch wide and an inch long. Hanging to the outer head-post was a pair of trousers (or overalls); one leg was quite bloody, and sticking to the cloth was a piece of bone about one inch wide and an inch and a half long. The head of the body was just under the edge of the bed, with the legs extending to the wall; one leg was drawn partly up, and one arm was under the body. I turned the body over, and found the nose flattened. We then removed the body to another room, and made the autopsy with results as follows:—

External appearances. The head and upper part of body were covered with dry blood. There was a large wound on the right side of the head, above and in front of the right ear, measuring three and three quarters by two and a quarter inches; from this wound brain substance was protruding. Another wound in the right frontal region measured two inches in length, and extended across the forehead. There was also a triangular wound, three fourths of an inch long and one fourth of an inch wide, just above the right eyebrow. No other wounds were found on the body. Rigor mortis was well marked, as was the cadaveric lividity on the front of body.

Internal appearances. On turning back the scalp a blood clot was found covering the whole right side of the head. Under the wounds were found fractures of the skull corresponding with the wounds. A number of loose pieces of bone were removed, one piece extending from lower part of large wound downwards, and in front of the right ear, measuring four and an eighth inches by one and a half inches. A fracture of the skull was found extending from the upper part of the large wound on the right side of the head towards the left ear, in a triangular shape, three and a half inches. On removing the skull the membranes were found destroyed under the large wound, and the whole right hemisphere was covered with a clot of blood. The larger part of the right hemisphere was lacerated. The rest of the brain was normal.

There were old pleuritic adhesions of the right lung in its posterior portion, and of the left at the apex; otherwise the lungs were normal, as were all other organs.

The cause of the death was thus determined to be a compound comminuted fracture of the skull, the result of violence. It was our opinion that the man was killed while lying on his left side in the bed; that he must have received a number of blows at the large wound to produce such a destruction, and that the blows must have been given just as the assailant came through the door of the bedroom, and in all probability were made while the victim was asleep, there being no signs of a tussle.

Some three weeks after this the son was arrested, when he confessed that he killed his father. He said that on the night of the 24th of September he (the son) came home about half past ten or eleven o'clock. His father began scolding about some work; from words they came to blows; his father struck him with the screw-driver, and then went into the bedroom. The blow so angered him (the son) that he went to a back room and got a hatchet, and going into the bedroom, as his father was sitting on the edge of the bed, he

concealed the hatchet, and as he passed he struck his father on the head twice or three times. The father fell over on the bed, and he did not strike him again. He saw what he had done, and threw the weapon into a pile of wood (where it was found by the officer), and broke open the cabinet expecting to find money. He then changed his clothes, taking about half an hour. He then left the house and went into the barn, where he slept over night. He drove the cows to pasture in the morning, and took the cars to Boston.

The case was tried at Plymouth in the spring of 1880. The son testified to the same facts as he had previously confessed. On cross-examination he said that his father was on the bed groaning when he left the house; that he did not put him on the floor. The medical expert for the defense said that the man could have lived as long as was testified, and had voluntary motion enough to throw himself out of bed. It is to be remembered that where the body lay in bed it was several inches lower than the edge, and the body was found with the head under the edge of the bed, and the trunk and feet away from it.

The government attorneys claimed that the man was killed in bed; that before leaving the house the son dragged him out of bed, and drew the foot of the bed out from the wall so that the body could not be seen from the windows, either at the foot of the bed or through one in the dining room opposite the door in the bedroom (a table being in the way). The son was found guilty of murder in the second degree, and is now at Concord. He said, when sentence was passed, he preferred death, and as the officer left him a few minutes on the morning of his leaving the jail he cut his throat, making five cuts; being in too great haste he did a poor job.

REPORT ON LAWS REGULATING THE PRACTICE OF MEDICINE IN THE UNITED STATES AND CANADA.¹

BY RICHARD J. DUNGLISON, M. D., AND HENRY O. MARCY, M. D.

THE progress made in the legislative restriction of medical practice in the United States since your committee was appointed, three years ago, to report upon the subject, has been both notable and salutary. At that time the propriety of establishing such laws was under active discussion, and weak enactments, temporizing in character and but partially effective in their action, were evoked from tardy and timorous legislators in several of the States of this country, as compromises between a sense of the necessity of doing something to protect the health of their constituents and a consciousness that the practitioners and supporters of quackery and of irregular methods of medical treatment were among the influential voters whose active opposition might jeopardize their reelection. It was also found to be impossible, in a few of the States, to establish regulations for the practice of medicine which would be shaped to the wishes, principles, or prejudices of those members of the legislatures who believed that they themselves were occasionally benefited by prescriptions that were not wholly scientific in their character, or by remedies that had acquired their reputation by extensive advertising of their supposed merits and efficacy. The legislation of the last year or two, however, seems tending to greater stringency, and to

¹ Report of a Committee read before the American Academy of Medicine at New York, October 10, 1883.

more adequate provision for the regulation of medical practice. Several States which had hitherto but feeble legal enactments, or possibly none at all, have, since our last report, adopted measures that will probably be found to be effective in their working and conducive to the public welfare. The excellent laws now in force in West Virginia and Illinois have been taken as models, and although it has been found impossible to imitate them exactly, on account of local obstacles and local prejudices, the wedge has been entered, and some good results must inevitably attend the enforcement of the law. A letter recently received from Dr. Millard, the secretary of the State Board of Minnesota, a State which has adopted restrictive enactments since the last annual report of your committee, summarizes the general aspects of the best of these laws; and we may quote his remarks upon their provisions as particularly appropriate in this connection, especially as he has given the subject of medical legislation close study and attention:—

"I think," says Dr. Millard, "the law or 'acts' now in force in West Virginia, Illinois, Minnesota, and Missouri, the best, by far, extant in any of the States. These four States are governed by virtually the same law, and have a constituency of at least 15,000 physicians. Each act gives the Board the power of deciding the diplomas of what schools they shall recognize, and of revoking the certificate of any practitioner for unprofessional conduct; also the power to grant licenses to non-graduates by passing the necessary examination to test their fitness. You will observe that the main features of the law of these four States make the Board the censors of the different medical schools, as well as the professional conduct of those practicing within the jurisdiction of the different Boards. It is claimed by the enemies of this act that it constitutes a 'medical autocracy' of the Board, and that it may use its power very unjustly. There is no doubt that, if the act is administered by unfair men, this criticism is true. It is, however, noticeable that outside of a few 'commercial' medical schools, the law gives the greatest satisfaction, and I have not heard a whisper of complaint. The profession in general, and a few of our leading medical institutions, recognize that this country is flooded with incompetent medical men. That the time has arrived to cry, halt! all will assent, but as to the means of bringing about the halt there is a great difference of opinion. That it will not be brought about by the colleges themselves the profession is satisfied, after the last ten years' agitation of the subject, and the example set by Bellevue and some others. In appealing to legislatures to regulate this evil, I think the correct law should compel *all parties* to submit to an examination before practicing in the State. Such legislation is, however, impracticable now, and next to this I think the acts of the States I have mentioned the best."

Whatever the character of a legislative enactment may be, the benefits to flow from it will necessarily depend upon the manner in which it may be enforced. . . . "Much disappointment has been expressed by physicians in Pennsylvania, as well as in New York, at the operation of the Registration Act, it being claimed that the practical result is that, instead of elevating the profession above irregulars and charlatans, it has degraded the regular practitioner to the level of any one who can register under the act, however unworthy he may be to be in the ranks of the medical

profession. It seems more than absurd that a physician may commit a crime that will render him in the eyes of the law unworthy to exercise the franchise of a freeman at the polls, and yet no bar exists to his continuing in practice, and no means are provided to annul or deprive him of the diploma he has dishonored."

The Mississippi State law, which was adopted in 1882, is stated, by an earnest observer in that section of the country,¹ to be on a par with that of Illinois, in its efficiency and practical working, and is said to have accomplished already all that its most sanguine friends could have expected. To quote his own language, "All practitioners in the State, as far as I am aware, of every grade, have cheerfully complied with all its requirements. . . . The pile doctors, down to the Indian doctor tramping around with his banjo and his calico gown, have given us a clear field. Their places are vacant, and their voice is heard no more in the land. Thus, already, in one season, thousands of dollars have been saved to the people of the State, to say nothing of other benefits."

As we must necessarily refer frequently to the conspicuous labors of the Illinois State Board, in any report intended to illustrate the operations of State laws for the relief of the public from the operations of unlicensed or legally unrecognized practitioners of medicine, in its various departments, we must briefly allude, at this moment, to its numerous refusals to extend its privileges to unworthy applicants for its recognition, and at the same time signify our appreciation of its efforts in a direction well worthy of our recognition as Fellows of the American Academy of Medicine, the attempt to secure a common examining board on preliminary education for all the medical schools of Chicago. To still further perfect its work, an effort was recently made in that State to secure the passage of a law which would rid the community of advertising and lecturing quacks.

A direct service to the medical profession throughout the country is being at this very moment executed by this Board, and especially by its very efficient and energetic Secretary, Dr. John H. Rauch, in the publication of an elaborate pamphlet on Medical Education and the Regulation of the Practice of Medicine in the United States and Canada, in which are embodied at length the details of all the laws now in force in the various States and Territories of the Union and in the Provinces of the Dominion of Canada. Each is herein represented in its present attitude, up to the very latest possible date of practicable information, and in numerous instances the opinions of official authorities as to the efficiency of the law are appended. Not only is the present phase of medical legislation thus made apparent at a glance, but medical education is portrayed, in the brief analysis of the course of instruction, requirements, etc., of each medical school recognized by the Illinois State Board, including, of course, all other colleges of the country which have a reputable standing through their chartered existence in each State. At the meeting of the Council of the American Academy of Medicine, in Philadelphia, in October last, the importance of such a work was so seriously recognized, as an outcome of the slight efforts in this direction made by your committee in their annual reports, that the secretary of the Academy was instructed to approach some of the leading publishing

¹ Dr. J. M. Taylor. Miss. Valley Med. Monthly, February, 1888

houses with the view of giving to the profession, as one of the labors of the Academy, a work that would embody all the laws regulating medical practice as they existed at that time. Fortunately an enterprising public body, the State Board of Health of Illinois, and its enthusiastic and valued Secretary, have now done what the publishers could not regard as a safe commercial venture, and the profession and public will doubtless be more liberally benefited by that more general mode of distribution. The good work thus executed by the Illinois Board will be the accepted authority for the profession on all points relative to medical education and practice in the United States.

It is not contemplated by your committee to enter into the details of the new laws enacted since the presentation of their last annual report. It may be briefly stated that the following States and Territories are now in the possession of laws, of various degrees of force and effectiveness, regulating the practice of medicine: Alabama, Arizona, Arkansas, California, Colorado, Connecticut, Delaware, District of Columbia, Florida, Georgia, Illinois, Kentucky, Louisiana, Maryland, Michigan, Minnesota, Mississippi, Missouri, Nebraska, Nevada, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Pennsylvania, South Carolina, Texas, Vermont, Virginia, and Wyoming. Canada has laws in operation in the Provinces of Manitoba, New Brunswick, Nova Scotia, Ontario, and Quebec. The States and Territories in which legislation has been established since the last annual report of this committee are Delaware, passed April 19, 1883; Michigan, which went into effect September 7, 1883; Minnesota, approved March 6, 1883; and Missouri, in effect from July, 1883. All of these recent enactments have elements to be commended, and if strictly enforced will undoubtedly command success in their execution. Of the States above mentioned in the general list, a few have weak and temporizing provisions. Pennsylvania still lags behind her sister States; her Legislature is content, for the present, with having adopted a simple registration law, which may have, and doubtless has, already accomplished a certain amount of good, and this has been accepted as the only present attainable and possible substitute for the stringent and restrictive measures which the profession and the public so urgently desire.

Of the peculiarities of construction or operation of some of the laws now in force much might be written in commendation or criticism; but the limits of this report render their recapitulation wholly impracticable. Sufficient is it to point out a few of these, in elucidation. In Alabama, for example, the diplomas of medical colleges confer no right to practice medicine in that State; the applicant must be actually examined by a board appointed for that purpose. In Arizona and Pennsylvania, and in Washington Territory, the law is simply for purposes of registration; in Arkansas a bill providing that all practitioners should be graduates of reputable medical colleges failed this year to pass both houses of the Legislature, and county boards of medical examiners, appointed by county judges, who may not be competent to decide as to the professional qualifications of their appointees, still continue to give certificates to applicants for permission to practice medicine in that State. Connecticut's very brief law is mainly intended for the punishment of itinerants. In Kentucky the law is a dead letter except in a few counties, and in Texas and Nebraska it is weak and ineffective.

Our Associate Fellow, Dr. Piffard, considers the New York law a good one, but that it has one important defect, in that a perjury in registering is only punishable as a misdemeanor, and not as a felony. Oregon has had a bill before the Legislature every year, for ten years past, but it has not yet succeeded in attaining so desirable a consummation. In Tennessee, which has no law of this kind, the practice of medicine is said to be free to all; according to the authority of the Secretary of the State Board of Health, "Indians, Negroes, confidence men, and all that ilk, ply their trade, with no restrictions whatever. Any man who claims to be a doctor is one; hence druggists who do not know enough to make a living turn out as doctors, in full practice, before you know it. A farmer boy, too lazy to plow, reads an old work on practice, or Every Man his Own Doctor, invests six dollars in drugs, and is a physician; and being a 'regular' we all consult with him. Our legislators will not touch, and our doctors are too timid to press, the subject, and so we languish in the old paths."

It may well be asked by us, as a committee watchful of the progress of the times, whether, in States like this, which have imposed no restrictions upon the unlimited and unbridled practice of medicine, the experience of nearly four centuries has seen any marked change from the days of King Henry VIII. to the present hour; ¹ for we read in the preamble of an act, passed in England in the year 1511, looking to the regulation of the practice of physic and surgery, that its enactment was rendered necessary by the fact that "the science and cunning of physick and surgery is daily, within this realm, exercised by a great multitude of ignorant persons, of whom the great part have no manner of insight in the same; some also can read no letters in the book, so far forth that common artificers, as smiths, weavers, and women, boldly and accustomedly take upon them great cures and things of great difficulty, in which they . . . apply such medicine as be very noxious and nothing meet therefore, to the high displeasure of God, great infamy to the faculty, and the grievous hurt, damage, and destruction of many of the king's liege people."

Utah has shown her interest in medical legislation only by that provision of her penal code which punishes physicians who are drunk, and has been content with this measure of legislative protection of the people of that section of the country. A correspondent in Salt Lake City ² writes that "the inference is, that during the little time he is sober he will not do much harm. As for the medical fraternity proper, I do not think any of them care for any law regulating medicine. I believe they are advocates of the doctrine of the 'survival of the fittest.'"

Wisconsin might be placed in the list of those having a law to regulate the practice of medicine, but the title indicates that it is simply "An Act to prevent Quacks from Deceiving the People by assuming a Professional Title," and not really a law that may be classed in the same category as those mentioned previously.

In a letter recently received from Dr. Rauch, Secretary of the Illinois State Board of Health, the following interesting remarks are made by him:—

"The following States may be said to have good

¹ W. T. Bly. Early English Medical and Surgical Legislation. New York Medical Record, September 1, 1883.

² Dr. H. J. Richards. Report of Illinois State Board.

laws, namely: North Carolina, Alabama, West Virginia, Illinois, Missouri, Minnesota, New Mexico, Wyoming Territory, Mississippi, Louisiana.

"Alabama requires *all* persons, both those holding diplomas, and those having none, to appear before the State or County Boards.

"North Carolina requires about the same, but the penalty for violation of the law is inadequate, and there is some complaint against it for that reason.

"The Mississippi law is new and cannot be well judged yet.

"After this year graduates of all colleges not complying with the requirements of this Board will be examined by the Board before being admitted to practice."

Such are the main points of interest connected with the progress of legislation in this country, which your committee have deemed it advisable to report. The facts there stated, in as comprehensive and condensed a manner as they have thought possible in their efforts to illustrate the progress of legal restrictions upon the practice of medicine, warrant them in expressing the view that commendable progress is being effected in this direction, and to entertain the belief that bright anticipation may be indulged for the future establishment of a healthy public sentiment that will in time protect the people themselves from the evils of irregular practice which they have blindly tolerated for so long a series of years.

PROGRESS IN DERMATOLOGY.

BY GEORGE H. TILDEN, M. D.

ALOPECIA FURFURACEA PRÆMATURA.

LASSAR and Bishop¹ published experiments which go to show that the ordinary alopecia furfuracea is an inoculable disease. The hairs which had fallen from the head of a patient suffering from this malady were mixed with vaseline and rubbed upon the skins of guinea-pigs and rabbits. The animals treated in this manner became bald, that is, lost their hair, in the regions of the body to which this mixture of diseased hair and vaseline had been applied. This condition of things began to be manifest about three weeks after the inoculation had been made, and the loss of hair was attended with desquamation. Hairs taken from these animals and rubbed into other and healthy animals produced a like result. Further particulars upon this subject were given by Lassar before the Berlin Medical Society.² Two examples of this disease were exhibited to the Society. Both the patients were young and exceptionally robust men, who for years had suffered from gradual and slowly increasing falling out of the hair of the head, attended by some itching of the scalp, and some desquamation thereof. Inoculation of hairs from the heads of these patients upon the skins of rabbits, guinea-pigs, and white mice had been sufficient to cause falling out of the hair in these animals. The above facts furnish ground for the assumption that this disease is locally infectious and inoculable, and to be treated by antimycotic methods. Opportunities for inoculation are furnished in plenty by the combs and brushes in use at barbers' shops, which, without any particular attention to cleanliness, are employed suc-

cessively upon different customers. Women are less subject to this affection than men, by reason of the fact that, as a rule, they dress their own hair and do not frequent barbers' shops.

The treatment recommended by Lassar is based upon the assumed character of the disease, and, although tiresome, appears to be efficient. The head is washed every day with tar soap or fluid glycerine soap for fifteen minutes, and the soap afterward removed by the liberal use of cold, followed by warm, water. A one fifth of one per cent. solution of corrosive sublimate is then thoroughly applied, the head dried, and into the scalp is rubbed a one half of one per cent. solution of B naphthol in alcohol. Finally the head is plentifully besmeared with about twenty-five grammes of a two per cent. solution of carbolic or salicylic acid in oil. This treatment must be followed with diligence for a long time. The first effect of treatment is apparent increase in the daily loss of hair, which, however, gradually diminishes, and in from two to three weeks ceases entirely, not to return, provided treatment is continued for some time longer. Eight weeks seems to be an adequate length of treatment in most cases, but even after this it is advisable to repeat the various applications once or twice a week for some weeks. In each one of fifty cases, inoculation of the disease upon animals was attended with success, and the foregoing method of treatment followed by good result. One case will serve as an example. In the beginning the amount of hair which was daily lost weighed 0.298 grammes; at the end of three months' treatment it weighed 0.0058 grammes. The reporter has found sulphur in an ointment containing ten per cent. to fifteen per cent. of the drug, as recommended by Unna,³ quite efficacious in the treatment of this affection.

PURPURA RHEUMATICA AND HEART DISEASE.

Schwartz, assistant in Kaposi's clinic, publishes⁴ two cases of purpura rheumatica complicated by acute insufficiency of the aortic valves. The patients were well-developed males nineteen and twenty-one years of age respectively. They were anæmic, and their only subjective sensations were general malaise and loss of appetite. They presented the characteristic eruption of purpura upon the lower extremities, the rest of the body being free. This eruption ran the usual course of purpuric eruptions, and disappeared in a few days after having gone through the characteristic changes of color, leaving behind pigmented spots. In each case the pulse and temperature were normal throughout the whole course of the disease. Physical examination gave no evidence of disease of any of the thoracic or abdominal viscera except the heart. In both instances there was evidence of aortic insufficiency, namely, a diastolic murmur of greatest intensity over the sternum and to the right of the sternum in the second intercostal space. In one case the second pulmonic sound was accentuated, and in both the jumping pulse of aortic insufficiency was to be felt. One case was seen after leaving the hospital, and evidence of compensatory hypertrophy of the left ventricle began to be manifest as early as four weeks after the beginning of the affection.

The fact that disorders of the heart may show themselves in connection with the various forms of erythema has been established by series of observations, and is

⁴ Wiener med. Wochenschrift, No. 32, August, 1883.

already well recognized. This is true not only of erythema exudativum multiforme but also of erythema nodosum and purpura rheumatica, and is evidence of the correctness of Hebra's and Kaposi's opinion that in spite of the manifold and different appearances of these eruptions they are to be regarded as symptoms of various grades of one and the same pathological process. Lewin, in his article upon Erythema Exudativum Multiforme,¹ mentions thirty cases of erythema, which were complicated by disease of the heart, in a total of one hundred and twenty-six cases. In the course of erythema one finds, as a rule, merely systolic murmurs at the base and apex of the heart, which do not in every instance admit of a clear and satisfactory explanation. The question as to whether an anæmic or febrile murmur does not in such cases simulate organic disease of the heart remains an open one so long as subsequent manifestations do not establish the diagnosis. The fact that in many cases the different varieties of erythema are accompanied with severe pain in the joints has led many, especially of the French observers, to regard these erythematous eruptions as rheumatic in character, and the attending heart affection as due to rheumatism. However plausible the above may seem in cases which are attended with high fever and pain, instances do occur like the two reported, where without any evidence of rheumatism, either in the history, the subjective or objective symptoms, disorder in the heart accompanies the manifestations upon the skin. The author is of the opinion that such cases go to show that the connection between the symptoms on the side of the heart and those of the skin is an intimate and peculiar one, and not to be referred to rheumatism.

CAUSES OF INFANTILE ECZEMA.

Heretofore the causation of eczema in children has been mainly ascribed to scrofula,² and instances of this disease which were manifestly not due to this condition have been accepted without any definite hypothesis as to their origin. Without doubt scrofula is responsible for numerous cases of eczema in children, but it does not account for the variety of the disease referred to by the author,³ which almost without exception manifests itself within the first half year of life, often during the initial months thereof, and which reaches its highest development at a period of infancy when scrofula does not usually exist. It is only in exceptional instances that eczema due to its influence occurs thus early in life. Infants which suffer from eczema as a rule show no signs of scrofula. They are to all appearances perfectly healthy children, well developed, well nourished, and very fat, while the skin, save in the affected regions, which are almost always the face and head, is smooth, soft, and supple. These infants are, in fact, models of good nourishment and health, and the tormenting itching caused by the disease does not prevent them from feeding well, and they gain in weight and flourish. The only bodily function which is not well performed is the evacuation of the bowels, and such infants are affected with costiveness due to intestinal torpidity. The movement of the bowels is of infrequent occurrence, and the stools are hard and of a light yellow or gray color, showing de-

ficiency in bile pigments. These infants are examples of "polysarcia adiposa," or the superabundant and universal formation of fat tissue. Upon percussion and palpation evidence of fatty infiltration of the liver, in the shape of increased size and firmer consistence of that organ, is not wanting, and in such cases as die from some intercurrent and acute affection fatty infiltrated liver is found at the autopsy. Healthy infants are disposed to the overformation and accumulation of fat tissue by reason of their diet and their limited mental and muscular development and activity. The connection in these cases between the above tendency and the development of eczema is one of cause and effect, and so long as the conditions exist which determine this tendency of infants to the excessive production of fat so long does the eczema which is caused by it persist, now better, now worse, in spite of ordinary methods of treatment. In many such cases treatment is given up in despair and the disease allowed to run its course. At the end of the first or during the beginning of the second year of life, when there is more mental and muscular action, and after the change to a more mixed and nitrogenous diet has been made, this exuberant production of fat ceases, and the fatty infiltration of the liver disappears. At the same time there is spontaneous recovery from eczema and from the torpid and inactive condition of the bowels which so often accompanies it. Sometimes, although rarely, this overproduction of fat is prolonged into the third or fourth year of life, in which case the eczema dependent upon it also persists either continuously or in intermittent attacks.

Assuming proneness to obesity to be the cause of eczema in these cases, the method of treatment is immediately indicated, and consists in limiting the quantity of fat-forming food which is taken. The "Banting process" has already been used in England as a remedy for certain forms of eczema occurring in adults. The common errors in connection with infants' diet consist in giving too much food and in the exclusive use of fat-forming food, and are the points to be looked after in these cases of infantile eczema. The food should be given less often, in smaller quantities at a time, and between the meals, composed of milk or some equivalent therefor, other meals, of food less liable to produce fat, namely, various broths and soups, should be provided. Attention to the sluggish condition of the bowels is very important in these cases, and in many will be of itself sufficient to effect a cure. For this purpose preparations of rhubarb or the syr. rhamni cathartici are useful. The good effect of cod-liver oil sometimes seen in such cases is to be ascribed to its loosening action upon the bowels rather than to any antiscorbutic quality. The regulation of the diet is often a very difficult matter, but as a rule it is easier of accomplishment when children are brought up by hand than when they are at the breast. In particularly obstinate cases, which are possibly due to hereditary tendencies, or when infants are for some reason unsuited to any but an exclusive milk diet, the internal administration of arsenic is oftentimes useful.

Why infantile obesity should cause eczema is not clear, the same tendency in adults not being attended with any development of this disease. The author is disposed to look for the connection in the inactive state of the bowels, which is almost a constant factor in infantile obesity, and which is probably due to deficient secretion of bile by reason of fatty infiltration of

¹ Charité-Annalen, iii. Jahrgang, 1878.

the liver. Such constipation causes the retention of waste material and of the glandular secretions which accumulate in the alimentary canal, and it is this condition of things to which the development of eczema is due. The reason why this variety of eczema is almost exclusively confined in its manifestation to the face and head is supposed to be the great determination of blood to these parts required by the development and growth of the skull, its contents, and appendages.

THE TUBERCLE BACILLUS AND LUPUS.

The opinion of Friedlander that lupus is tuberculosis of the skin, an opinion based upon the identity in structure of the nodule of lupus and tubercle, has not as yet been generally accepted. Doutrelepon¹ was induced to examine specimens of lupus, with regard to the presence or absence therein of the specific bacillus of tuberculosis, by the fact that there came under his observation the case of a healthy man who suddenly died of basilar tubercular meningitis, the only possible source of infection being lupus of the face and extremities. Demme² had previously reported that in three cases of lupus he found in the nodules peculiar to the disease large numbers of tubercle bacilli. The most effective method of demonstrating the presence of these bacilli is stated by Doutrelepon to be excision of a portion of diseased skin, hardening it in absolute alcohol, and making sections through the lupus nodules with a microtome. These sections were colored by Koch's method, and put up in Canada balsam. Bits of skin taken from seven cases of lupus were prepared in this manner and examined, with positive result in every instance. The bacilli were to be seen scattered about and arranged in groups of a dozen or more, as a rule situated between the cells which made up the lupus nodules, also inside the cells. None were detected in the giant cells, but around these the bacilli were thickly gathered. Pfeiffer³ has also reported the discovery of the tubercle bacillus in two out of eight specimens which had been made from bits of lupus granulation taken from the conjunctiva of a young girl.

The investigations of Martin, Koch, and Cornil have demonstrated the fact that the introduction of bits of tuberculous matter into the peritoneal cavity of animals, guinea-pigs in particular, is always followed by tuberculosis of the peritonæum, which, as a rule, begins in the region of the spleen and becomes generalized in the peritonæum in about six weeks, resulting in well-marked pulmonary tuberculosis by the end of two months. Upon the supposition that lupus, if of tuberculous nature, would produce a like result, Leloir⁴ reported to the Société de Biologie the inoculation in this manner of fifteen guinea-pigs, each experiment having been followed by negative result. Six months later, in July, 1883, Cornil and Leloir presented to the same Society the results of the intraperitoneal inoculation of animals with lupus material as follows:—

Sixteen guinea-pigs were inoculated with material taken from cases of lupus vulgaris, and two with matter furnished by cases of lupus erythematosus. Of the first lot of guinea-pigs ten died or were killed some months after inoculation, and of these ten but three were found to be infected with tuberculosis. In two

of the animals in which inoculation was attended with success, the tuberculosis was general, and in the other were found tubercles only of the spleen and mesenteric glands, and in all three of these animals the bacillus of tubercle was found in quantities. Inoculation from the two cases of generalized tuberculosis upon other and healthy animals was attended with success in one instance, and from this last animal successful inoculation was also made. Of the two guinea-pigs inoculated with material from lupus erythematosus, one died in one month, and was found to be affected with general miliary tuberculosis. The other lived, and three months after the experiment was in good health.

The micrococci which were found in lupus by Schüller⁵ are considered by Cornil and Leloir to be "mastzellen." These observers have also examined portions of diseased skin taken from eleven patients affected with lupus vulgaris, and have detected the tubercle bacillus in but one instance, in which case there was also evidence of pulmonary tuberculosis, while all the others were free from this disease. Their conclusion is that if the bacillus of tubercle is present in lupus, it is at all events extremely uncommon. The rarity of any positive result from the inoculation of lupus material, and the long period of time which ensues between inoculation and the manifestation of tuberculous infection as compared with instances where ordinary tuberculous material is employed, support them in this view and lead them to the conclusion that if lupus is localized tuberculosis, it is tuberculosis "très atténuée."

The above communication to the Société de Biologie was followed by a discussion of which the following is a résumé:—

Bert said that it would be interesting to know whether the guinea-pigs in which the inoculation had been followed by negative results were vaccinated as regards tuberculosis.

Cornil replied that several of these animals had been preserved, and that it was his intention to inoculate them with the most virulent sort of tuberculous material.

Melassez stated that he had never detected the bacillus of tubercle in the specimens of lupus tissue which he had examined, and that the inoculation of lupus material, in the anterior chamber of the eyes of rabbits, had been followed by negative results.

Grancher thought that the experience of Cornil with inoculation of lupus was similar to that of Pasteur with charbon. The latter found that the inoculation of an infinitesimal quantity of the bacillus of charbon was followed by the evolution of this disease, but much more slowly than when larger quantities were used. According to Cornil the same relation held between the inoculation of lupus and of ordinary tuberculous material, and lupus might be looked upon as an attenuated form of tuberculosis. He considered this as further evidence of the identity of scrofula and tuberculosis. Scrofula he regarded as a variety of tuberculosis which manifested itself in special directions. He was skeptical as to the possibility of vaccination against tuberculosis.

Vidal, from a clinical point of view, was unwilling to allow the existence of any connection between lupus and tuberculosis. He thought that the differences between the ulcerations of lupus and those of tubercle, especially upon mucous membrane, were too marked to admit of identity in the two pathological processes.

⁵ Vide Derm. Report in this Journal, May 4, 1882.

Cornil thought that evidence sufficient to justify final judgment in this matter was yet wanting, and that the part of wisdom was to wait. Nevertheless he considered that there were grounds for hoping that inoculation of lupus material would serve as vaccination against tuberculosis. For this it was not necessary that the two processes should be identical. Vaccinia is far from being the same as small-pox, and yet its preventive action is incontestable. A similar relation may exist between lupus and tubercle.

Bert regarded this view as very likely the true one. After every inoculation of virus there ensues a struggle between the animal and the poison. This struggle may terminate either in the rapid death of the animal, which means the triumph of the micro-organism, or by the survival and victory of the animal. If the micro-organism is rapidly destroyed there is no struggle, so to speak, and no vaccination, but if the micro-organism remains in existence long enough to cause certain manifestations, in the latter case the animal may be considered as vaccinated.

Schuchardt and Krause¹ have examined, with special reference to the presence of the tubercle bacillus, a large number of specimens of "surgical tuberculosis" collected from Volkmann's clinic with successful results. Among these specimens, which comprised synovial and bone tuberculosis, tuberculous abscesses, in which bacilli were found in the lining membrane, but not in the pus contained therein, tuberculosis of the lymph glands, etc., there were three instances of tuberculosis of the skin and lupus.

Note by the Reporter. The identity in the anatomical structure of the nodule of lupus and of tubercle, taken together with the fact that the micro-organism found in each appears to be the same, furnishes strong presumptive evidence that lupus is localized tuberculosis of the skin. The supposition that lupus is cutaneous tuberculosis is not upset by the arguments which go to show that it has no special connection with inherited tuberculosis, it being found combined with the latter only in from ten to fifteen per cent. of cases. Human tuberculosis in any situation is usually a localized process which seems to find in the lungs the most favorable conditions for its propagation and development. The bacillus of tubercle is capable of evolution only under certain conditions of tissue and environment, within a narrow range of temperature. The conditions which obtain in the skin are manifestly hostile to its welfare as compared with those furnished by the lungs, and account for the uncommon occurrence of lupus and its extremely slow advance. The fact that lupus usually manifests itself early in life seems to indicate that the skin loses its susceptibility to the influence of the bacillus by age, or, in other words, furnishes less favorable conditions for its development. Such susceptibility of the skin must either be inherited or acquired, for it is evidently not common to all individuals. There is nothing to show that it is inherited, and everything is against this supposition, but the facts that in a large proportion of cases lupus is developed only in the neighborhood of cicatrices due to scrofulous disease, or upon mucous membranes already altered by catarrhal processes, and that in not a few instances injury or attacks of erysipelas seem to immediately precede the first appearance of the disease, signify that such peculiarity of skin and mucous membrane is acquired by reason of antecedent pathological

processes. The above facts were regarded by Raudnitz² as going to show that lupus is due to a localized specific predisposition, but in the light of recent knowledge they indicate an acquired and local predisposition to a special form of infection. It is certain, at all events, that such cutaneous susceptibility does not carry with it or imply predisposition to ordinary tuberculous infection, which manifests itself in the lungs. Experiments with animals go to show that the ordinary method of infection in pulmonary tuberculosis is by inspired air, and they also demonstrate the marked influence of local predisposition of the lungs in determining the situation of tuberculous infection. The common initial seat of lupus in the skin and mucous membrane of the nostrils would suggest the same method of infection as probably obtains in pulmonary tuberculosis, lupus, however, being exceedingly uncommon in comparison with phthisis by reason of the adverse surroundings which the skin offers to the development of the tubercle bacillus.

SKIN DISEASES OF NERVOUS ORIGIN.³

This book is a very interesting and valuable one, and indicates the tendency of recent investigation to seek for the pathogenesis of cutaneous disease in the labyrinth of neuro-pathology. Particular attention is given by the author to the sympathetic nervous system and its dependent vaso-motor and trophic nerves in their relations with affections of the skin. The first part of the book is concerned with the above system and its physiological and pathological connection with dermal disturbances, and the last portion is devoted to the consideration of skin diseases of a nervous origin, many interesting and instructive instances of which are given, while all that is known about them is presented. They are divided by the author into three main classes:—

- (1.) Vaso-motor affections of the skin.
- (2.) Tropho-neurotic affections of the skin.
- (3.) Idio-neurotic affections of the skin.

The work is of more value as coming from a trained dermatologist, a pupil of Hebra, and its only fault is the final attempt to arrange a classification of cutaneous diseases which is based upon their neuro-pathology. The author admits that it is merely an attempt, but inasmuch as *all* skin diseases are not due to, or accompanied by, changes in the nervous system, such a classification must always be incomplete and inadequate. A classification founded upon ætiology would no doubt be desirable, but in the present state of our knowledge the soundest basis for dermatological classification is pathological anatomy, not pathogenesis, and other systems, however praiseworthy as tentative though incomplete efforts towards the truth, are only to be regarded as such. The mania for classification which seizes upon dermatologists above other men is curious, but significant of the unsatisfactory nature of even the best system, which is that of Hebra and its various modifications.

— A severe epidemic of trichinosis is reported from Emaleben, Russian Saxony, the disease being said to prevail in eighty-four of the 134 houses in the town. A considerable number of deaths are reported.

Reports of Societies.**SUFFOLK DISTRICT MEDICAL SOCIETY.****SURGICAL SECTION.**

WILLIAM N. BULLARD, M. D., SECRETARY PRO TEM.

OCTOBER 13, 1883. The meeting was called to order at eight P. M. DR. D. W. CHEEVER in the chair.

INTERNAL URETHROTOMY BY OTIS'S METHOD.¹

DR. F. S. WATSON read a paper on Nineteen Cases of Internal Urethrotomy by Otis's Method, with Remarks.

DR. TILDEN stated that the experience of Dr. Watson and himself confirmed the statement that the larger proportion of strictures occurred in the anterior urethra, within five inches of the meatus. Within this region of the urethra there were two points where strictures were more common than elsewhere, namely, behind the meatus, within one inch of it, and at a region between two and a half and three and a half inches from the meatus, the latter region corresponding to the peno-scrotal junction. If fluid be forced through a flexible tube with collapsed walls like the urethra friction is caused, and this friction may be increased at any point either by diminishing the calibre of the tube at that point or by bending the tube, which is practically the same thing. This condition is just what exists in the urethra behind the meatus, which on the average is one fourth smaller than the canal behind it, and at the peno-scrotal junction where the urethra takes a sharp bend. The increased friction at these two points does no harm so long as the urethra is in a healthy condition, but as soon as inflammation has been set up in the canal it, in many cases, causes perpetuation of inflammation. This means the formation of granulation tissue, and granulation tissue eventually results in stricture. This seems to be the reason why strictures come first at these two points in the canal. After a stricture has once formed it may cause the formation of a stricture behind it, and in this way the urethra may be filled with strictures. The most important point about the operation is the avoidance of urethritis. Urethritis is bad not only as causing chordee, but also as imperiling the permanent good result of the operation. The wound made by the urethrotome is a spindle-shaped affair, which, if it heals without urethritis, becomes covered with a thin, soft, non-retractile cicatrix. If urethritis occurs a different and undesirable sort of cicatrix may result. The points in avoidance of urethritis are three: reducing any existing discharge to a minimum, which can always be done if time be taken; not using the urethrotome as a divulsor, as it is purely a cutting, not a tearing, instrument; and using perfectly clean instruments.

DR. GREENOUGH said that he considered that the necessity of after-treatment was usually not sufficiently insisted upon. He did not see why the tissue formed over the wound after Otis's operation should in any way differ from that produced by any other mode of operating. He then mentioned the case of a patient who had two very tight strictures, which, however, yielded well to dilatation. On account of special circumstances Maisonneuve's operation was performed. Three or four years afterwards, the patient having

neglected to pass sounds, recontraction occurred. Whatever method be employed recurrence is liable unless sounds are constantly used.

DR. TILDEN said that non-retracting tissue meant the absence of urethritis.

DR. WATSON referred to some observations on wounds resulting from internal urethrotomy by M. Maurice Perrin.

DR. GREENOUGH said that the paper under discussion was of interest in two points, namely, in regard to the value of the operation itself, and in regard to the indications for operating at all. He considered it very questionable whether it was often worth while to operate at all in the case of a healthy man. In any case the patient should never be assured of absolute freedom from danger in any of the operations. There is a great difference between private and hospital patients in regard to operating, and in private cases gradual dilatation was often the best mode of treatment.

DR. GARLAND spoke on the subject of the recurrence of strictures. The line which Otis draws between recurrent and non-recurrent strictures is that in the latter case the stricture has been completely cut through, in the former only partially so. If the section has been complete the stricture disappears, and nearly normal tissue is left, and this irrespective of the passing of sounds. The wound will in many cases heal kindly in ten days. If the stricture be not sufficiently cut there is great liability of return. Dr. Garland said that there was always danger in meddling with the urethra, and gave examples of unfortunate results and complications following gradual dilatation, among the latter swelled testicle and pericarditis. He considered cutting equally safe with dilatation.

DR. MIXTER showed several casts of the urethra made by Dr. Richardson and himself in both plaster and fusible metal. These show the shape and varying calibre of the urethra in its different portions. Near the meatus is the fossa navicularis, which is shown to be a shallow, well-marked pocket rather than a dilatation. Behind this the calibre is quite regular until the bulbous portion is reached, where there is a fusiform enlargement nearly twice the diameter of the urethra in front of it.

The membranous portion is the narrowest part of the canal. This is divided from the prostatic portion by a well-marked fold of mucous membrane, which is shown in a number of the casts, and which, starting on the under surface of the urethra, passes upward and forward to meet on its upper surface.

This fold seems to be quite constant, as shown by the casts made, though it is not described in the anatomies.

The prostatic urethra presents a considerable dilatation, triangular on section, the floor being marked by the caput gallinaginis. Diagrams of this portion of the urethra give but a slight idea of the shape of the cavity. At the point where the prostatic urethra joins the bladder is a well-marked constriction of the canal, which is here little larger than at its membranous portion.

DR. G. W. GAY stated that his experience of Otis's operation in his first three cases had been discouraging. In all symptoms of septicæmia or pyæmia had followed the operation. Since then he had used a modified form of the operation. He never measured the penis nor urethra. He used a curved bistoury in preference

¹ See page 385 of this number of the JOURNAL.

to the straight one. In the cases operated on by the modified method he had had no trouble. The after-treatment was important. One half to one quarter of a grain of morphia was given about half an hour after the operation, and quinine gr. x.-xx. within a few hours. Dr. Gay found a larger proportion of strictures in the membranous portion of the urethra than Dr. Watson had seemed inclined to admit. He thought that what was specially needed was some method for operating on deep strictures. If an ordinary stricture could be easily dilated he should hesitate to advise cutting; if the stricture were resilient or irritable cutting would be advisable. All strictures, however treated, do not recontract nor give trouble during the life of the patient.

With regard to the cases mentioned by Dr. Gay, DR. TILDEN said that it seemed to him that the reason that they had been attended with such bad results was that in these cases the instrument had been used as a divulsor, not as a urethrotome. The cases had been published, and according to Dr. Gay's description the strictures were first cut, and then the dilating instrument had been at once screwed up to the full size of the canal. This was divulsion in its worst form. In ordinary divulsion the force is applied equally in all directions, but in the above operation the force was applied in only two directions, one of which was already weakened by an initiatory cut. Such a wound might extend anywhere, and be good ground for pyæmia and the absorption of septic material, such as had happened in these cases.

DR. BRADFORD mentioned a case under his care operated upon by Dr. Tilden in which there was suppression of urine for thirty-six hours after cutting, though eventually there was a perfect recovery. The arteries in this patient were found to be atheromatous. If one takes into consideration the statistics of Dr. Weir from 500 cases Otis's operation may be regarded as safe as divulsion.

In answer to a question, DR. WATSON said that all well-organized strictures situated anterior to the bulbous portion of the urethra were suited for internal urethrotomy. The cases which gave especially good results from gradual dilatation he believed to be such narrowings of the canal as were composed of granulation tissue or of stricture tissue in its early stages of formation. The difference between the latter and those in a somewhat more advanced stage of formation often escaped observation unless they were carefully examined by the bougie à boule. The more irritable and resilient the stricture the more striking was the result by internal urethrotomy as compared with that by any other method. If one believed in the possibility of permanent cure of stricture by an internal urethrotomy, and admitted the impossibility of a permanent cure by any other method, his judgment would lean strongly toward the former method of treatment, even though there were an increased risk in the procedure, provided such risk were slight. The advocates of internal urethrotomy, however, deny the existence of such risk when the operation is properly performed.

DR. CHEEVER said that he believed that the causes which had operated against the performance of internal urethrotomy in this city were (1) because the operation had been performed with a curved bistoury, and (2) because no distinction between the deeper-seated and the more anterior strictures had been made, and consequently in many cases severe hæmorrhage had occurred.

The earlier operations for cutting preceded divulsion. In early days there were three methods of treating strictures,—gradual dilatation, external urethrotomy (Syme), and internal urethrotomy as practiced by the French surgeons. The latter was a bold operation, produced hæmorrhage frequently, was often fatal, and finally abandoned as unsafe. The operation as described to-night was reasonably safe, but when first introduced by Otis the precautions described by the reader were not used, no measurements were taken, there was no previous treatment, the operation was often performed in the surgeon's office, and the patient walked home afterwards.

The most important question in regard to the operations for stricture was the permanence of the results. Some strictures do not recontract, at least for a long time, as in a case described, where there was recontraction only after fifty-three years. Most patients improve after treatment, but finally neglect proper precautions and permit gradual recontraction.

In urethrotomy it is wiser not to retain the catheter. Fistula is apt to result, and it always causes irritation, while the urine escapes beside it. Most persons able to walk about can get on well with gradual dilatation unless they have an irritable nervous system and irritable urethra.

TÆNIA MEDIO-CANCELLATA.

The discussion on the preceding paper being closed, DR. GARLAND showed a specimen of tænia medio-cancellata, with the head, which he had obtained by means of pelletierine, an alkaloid obtained by M. Turret from the bark of the pomegranate. A preparation of this is made, and the dose for an adult is a bottle which costs three dollars. Dr. Garland reported two successful cases in which he had used it.

AMERICAN ACADEMY OF MEDICINE.

THE American Academy of Medicine held its eighth annual meeting October 9th and 10th, at the hall of the New York Academy of Medicine. In the afternoon of the first day papers were read by Drs. TRAILL GREEN, of Easton, Penn., BENJAMIN LEE, of Philadelphia, CHARLES MCINTYRE, JR., of Easton, Penn., A. D. ROCKWELL, of New York, and A. L. GIBON, of the United States Navy.

DR. GREEN's subject was

THE INSUFFICIENCY OF TECHNICAL TRAINING AS A MEANS OF MENTAL CULTURE,

and he strongly advocated the study of the classics, mathematics, and the various branches ordinarily taught in the large colleges as an indispensable preliminary to purely professional education.

DR. LEE made a plea for the more general and thorough study of the subject of botany on the part of medical students; and the other papers (with the exception of Dr. Rockwell's, which consisted of an eulogy of the late Dr. George M. Beard) were devoted to a consideration of the best means for elevating the standard of the profession, and excluding from it ignorant and unworthy individuals.

In the evening

THE ANNUAL ADDRESS

before the Academy was delivered by the President, DR. H. O. MARCY, of Boston. His subject was, The

Recent Advances of Sanitary Science: the Relations of Micro-organisms to Disease; and it was illustrated by micro-photographs projected upon the screen. A considerable portion of it was devoted to the question of sewage in New York, Boston, and other large cities.

The first paper of the second day's session was by DR. L. S. PILCHER, on

THE RELATIONS OF MEDICAL JOURNALISM TO HIGHER MEDICAL EDUCATION IN AMERICA.

Before reading it he made some remarks suggested by the papers of the previous day, in which he opposed the strict interpretation of the principles upon which the Academy was founded, chief among which is the encouragement of classical, mathematical, and scientific training among those professing to pursue a course of medical study. There was no doubt, he said, that those physicians who lacked the advantages of general culture in youth regretted the fact, but it was not in the power of the Academy to decide that the avenues of advancement in the profession should be closed to all who had not attained a certain arbitrary standard of learning. Some men of college training made incapable physicians, and some men rose from the plow and the anvil to places of distinction as medical practitioners. To have made the humanities an indispensable requisite to a degree in medicine would have excluded such men as John Hunter and Sir Astley Cooper from the profession in which they won such imperishable fame. To be a scientist was not necessarily to be a good practitioner. Harvey's medical practice was the laughing-stock of London; while Sydenham, inferior as a scholar and savant, was incalculably superior in the practical work of curing disease. The discussion was continued by DRs. HUNT, of Boston, STEINER, of Maryland, GIHON and SIBBET, and closed by Dr. Pilcher.

DR. HUNT denounced the whole system of academical education as mediæval, inconsequential, and worthless. He was not a Fellow of the Academy himself, but he thought that that body was wasting its time in endeavoring to arrest a progress that was inevitable. College life was simply four years of play, which left a young man less fitted for professional study than he was before his freshman year.

DR. J. CHESTON MORRIS, of Philadelphia, read a paper on

THE MILK SUPPLY IN LARGE CITIES.

In London, he said, many families had been obliged to have the cow brought to the door of the house, and see the milk drawn before them in order to be sure that it was pure. In our own large cities no one who observed the settlements in the large milk cans could say there were no "grounds" of complaint. He believed that the proper way to prevent the dilution and adulteration of milk was to oblige milkmen to sell it in sealed jars marked with their names and addresses. By the use of small sealed jars also milk could be conveyed hundreds of miles in good condition, thus enlarging the territory from which the supply for a large city could be obtained. He pursued this method on his own farms near Philadelphia, the milk supply of which place, he thought, was probably better than that of any other large city in the United States. The first thing to do in the way of improvement everywhere was to convince the people that the cheapest milk was not the best. The farmers could not furnish good milk at a less average cost than from four to five

cents a quart, yet the dealers at present would pay only three cents in summer, and from four and a half to five cents in winter. By means of the sealed jars, he said, he had sent milk from Westchester County, Penn., to Aiken, S. C., which, after the three days' journey, proved fresh and sweet, and in the summer he sent milk daily to Atlantic City, a distance of ninety miles. The name and address on the jar placed the responsibility for bad milk where it belonged.

Papers were then read by DR. ROCKWELL on the Value of Electolysis, and DR. R. S. SUTTON, of Pittsburgh, on The Necessity of Cleanliness in Surgical Operations, and DR. KAISER read for Dr. Lewis P. Bush, of Wilmington, Del., a paper entitled, Some Thoughts on Vaccination, in which the writer expressed his belief in the necessity of compulsory vaccination, and claimed that no child who had not been vaccinated should be allowed to enter a public school.

DRs. DUNGLISON and MARCY presented a report on

THE PROGRESS MADE BY THE STATES OF THE UNION IN MEDICAL LEGISLATION,¹

in which the registration laws of New York and Pennsylvania were described as only partially successful. The States whose Legislatures had passed more or less efficient laws in regard to the practice of medicine since the last annual meeting of the Academy were Delaware, Michigan, Minnesota, and Missouri.

ELECTION OF OFFICERS.

The following officers were elected for the ensuing year: President, Dr. Benjamin Lee, of Philadelphia; Vice-Presidents, Drs. A. L. Gihon, U. S. N., Nathan Allen, George F. Shrad, and E. J. Bermingham, of New York; Secretary and Treasurer, Dr. R. J. Dunglison, of Philadelphia; Assistant Secretary, Dr. Charles McIntyre, Jr., of Easton, Penn.

The President appointed as members of the Council, Drs. Charles C. Lee, of New York, William Elmer, of Trenton, N. J., and J. Cheston Morris, of Philadelphia. And it was announced that the next meeting of the Academy would be in Baltimore.

Recent Literature.

A Complete Hand-book of Treatment, Arranged as an Alphabetical Index of Diseases to Facilitate Reference, and Containing nearly One Thousand Formulae. By WILLIAM AITKEN, M. D. (Edin.), F. R. S. New York: Bermingham & Co. 1882.

This book, of about 450 pages, is composed of the chapters on Treatment, taken from the latest edition of Dr. Aitken's Science and Practice of Medicine, which have been somewhat revised and rearranged to make them more convenient for reference.

Training-schools for Nurses, with Notes on Twenty-two Schools. By W. G. THOMPSON, M. D. New York: G. P. Putnam's Sons. 1883.

A little book of the primer style, the first third, or eighteen pages, of which is occupied by an introductory account of nursing in general, and a general description of the organization of American training-schools. The rest of the book is composed of notes on twenty-two different schools in the United States, of several schools of midwifery, and of the Directory of Nurses in Boston and Philadelphia.

Medical and Surgical Journal.

THURSDAY, OCTOBER 25, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

RAILWAY SPINE.

IN this iconoclastic age when we are not allowed to believe in a personal Devil or good honest ghosts, or even to coddle our own pet superstitions and hobbies without a suspicion of mental degeneration, it is natural that the medical "bugaboo" raised by Mr. Erichsen some years ago, and christened spinal concussion, should meet with little quarter at the hands of the modern scientific observer. It is possible, however, that in this, as in other things, the skeptic may have gone too far, and that although it was no ghost that has alarmed us there may actually have been some phosphorescent light which we do not understand, and the nature of which we cannot fully explain. The cases reported recently in the JOURNAL by Dr. J. J. Putnam, and the paper in a late issue by Dr. Walton, point to the reality of a set of symptoms induced by traumatism which corresponds well with those hitherto termed spinal concussion, a name so misleading that many accurate observers through the influence of the name alone have been induced to deny the existence of what the name covers. A rose, however, under any other name will remain as fragrant to the sufferer, and whether the ailment be termed railway spine, or traumatic neurasthenia, or hysterical hemianæsthesia, the condition is equally distressing.

Mr. Erichsen's book undoubtedly led to an exaggeration of the dangers of a certain class of railway accidents, and gave a pretext for a great many unwarranted assaults on railway corporations. While, representing the reaction, Mr. Page's recent work certainly favors an undue belief in the certainty of recovery in cases of this sort. Erb presents the matter rather more fairly than either of these writers. Accidents which occur in railway collisions, as other accidents, may lead to a long train of nervous symptoms, and when death has resulted a post-mortem examination may reveal little apparent cause for the fatal result. In a few cases the evidence of a chronic meningitis of the cord was found. In the greater number of these cases the pathology is a riddle, which for its satisfactory solution will need a great deal of experiment and careful and extensive post-mortem investigation. Before accepting the actual identity between what is called hysteria and certain forms of spinal concussion, or, as suggested by Dr. Walton, regarding the railway spine as really a railway head, it is necessary to have

a clearer idea as to what hysteria actually is, and in general what part the brain plays as a central origin for some of the less marked nervous phenomena hitherto supposed to radiate from the cord.

The chief practical difficulty, however, encountered in these cases is not in determining whether the hyperæsthesia or the localized anæsthesia results from changes in the cord or in the brain, or whether the symptoms are to be regarded as organic or functional, but whether they are actual or feigned. But little is written in the ordinary medical text-books on malingering in these cases for two reasons: first because the physician's bias is to regard a patient's manifestation of pain as genuine, or at least as "nervous" or exaggerated, and, second, because the directions for the detection of malingering in these cases frequently would rather belong to a detective's manual than to a medical essay, involving as they would the questions of motive, previous personal character, and veracity. Usually the patient's symptoms are of such a nature, and so consistent or inconsistent with the ordinary types of disease, that the observer can arrive at the truth as to shamming by the process of reasonable conjecture; but given an intelligent and unscrupulous man with the prospect of a large award to be earned by his skill as a malingerer, and the opportunity for instruction afforded by the number of physicians usually called to examine such cases by the friends, the lawyers, and the family doctors, the result is frequently a puzzle which has not only to be guessed at and treated on the doctrine of chances, but explained before a non-medical audience unaccustomed to the shades of medical diagnosis, and inclined to regard doctors as a class of illogical men who disagree.

The needed clinical work, it seems to us, in the study of "railway spine" is the determination of clearly defined types of the disease, and the investigations of the variants from this type, and the certain relation of objective symptoms to the disease. The localizations of the central lesions and the pathological changes represented by certain symptoms furnishes interesting problems, but before we attempt to discover the North Pole let us develop Central Africa. All attempts, however, to get at a rational explanation of the peculiar features of this riddle of a disease must be regarded as of value, and the recent attention paid by neurologists to the subject is heartily welcome.

THE CONVERSION OF MALIGNANT TUMORS INTO INNOCENT GROWTHS, AND THE ADVANTAGES OF INCANDESCENT INSTRUMENTS.

PROFESSOR DR. V. NUSSBAUM recently delivered a notable clinical lecture in Munich,¹ in which he introduced one of the most important questions which can claim the attention of the medical profession, and he believes he has already taken an initial step toward its solution. To Thiersch belongs the credit of first directing the thoughts of surgeons in this direction by

¹ Wien. med. Zeit., June 3, 1883.

the memorable words, "We are justified in entertaining the hope for the discovery of a method of treatment for the positive cure of cancer if we can succeed in employing some means for a considerable time which shall act upon the tissue elements of the disease in such a way as to restrain their proliferation without causing their death (necrosis)." After attempts with many substances (injections of silver nitrate, pepsin, acetic acid, etc.) which proved entirely futile, Nussbaum now believes that he has discovered a procedure which answers the requirements of Thiersch, and which has already yielded very promising results in its practical application.

Professor Nussbaum adds, "It appears to me that a total interruption of all peripheral sources of nutrition is the means best adapted to restrain the proliferation of tissue elements without at the same time destroying their vitality. This object is best accomplished by the use of the thermo-cautery, with which instrument a deep channel is made quite around the malignant growth, thus cutting off entirely the supply of blood and other nutritive fluids from the surrounding tissues. The small vessels which ascend into the tumor from the parts beneath are sufficient to preserve its vitality so that gangrene does not occur. The thermo-cautery is far preferable to the ligature, and possesses many advantages over the knife. The hot iron and the various chemical caustics are worthy of more extensive employment in the domain of malignant growths than they have ever enjoyed."

Professor Nussbaum adds, "I do not doubt that thus circumscribing a cancerous growth, thus cutting off every channel of peripheral nutrition, has a brilliant future, especially in those desperate cases in which death is imminent from hemorrhage." He gives the report of two cases in his own practice to emphasize this point. Also in cases in which the enfeebled condition of the patient forbids the thought of any operative measures for the removal of the growth this process finds an indication. At all events the cutting off of the peripheral blood supply has afforded, he reports, such unexpected and astonishing results that he earnestly recommends this procedure to the attention and practice of all those having occasion to treat a case adapted to its employment.

The entire lecture is worthy careful reading by every surgeon, though it is probable much difference of opinion would be entertained in regard to the views expressed. So eminent an authority and fellow countryman of Nussbaum's as Prof. V. Langenbeck declared himself opposed to them in the course of a discussion on cancer of the breast at the late Congress of German Surgeons at Berlin. V. Langenbeck thinks that a clean operation can be much better performed with the knife than with the thermo-cautery, cauterization causing greater suppuration, which again favors infection.

— We are glad to hear that Dr. Fisher, Superintendent of the Tewksbury Almshouse, has not been so ill as was currently reported, and is now convalescent.

MEDICAL NOTES.

— Owing to the space demanded in the second part of to-day's issue of the JOURNAL by the report of the proceedings at the dedication of the Harvard Medical School an editorial on the annual report of the Tewksbury Almshouse has had to be omitted.

— A contemporary quotes Dr. Da Costa as saying, "If one has not too much to do, he writes a short paper on phthisis; if one has little to do, he writes a long paper on phthisis; if one has nothing to do, he writes a book on phthisis." The same writer says: "Gynecologists, as a rule, part their hair and their names in the middle, and never die until they have invented pessaries and speculums innumerable."

— The Scottish correspondent of the *Lancet* relates some instances of emotional disease rather novel, as he says, so far north. They consist of feigning death. The writer says: "One case occurred in Dunfermline, the other in Edinburgh; but probably the latter city will not in the future be considered a fitting field for the operations of these malingerers. The woman who had there feigned serious illness in the police cells, and formerly fainting fits, was actually conveyed to the infirmary, and then assumed a death-like state. A threat, however, to remove the body to the mortuary, aided by an energetic galvanic shock, was quickly effective, though similar treatment had again to be resorted to in the police cells. The interesting Dunfermline visitor, who was certainly not a Blue Ribbonite, caused some confusion in the prison during the night by indulging in certain fits to such an extent that the doctor was sent for. This gentleman — probably after a very hurried inspection — stated that death had occurred some hours before, and a post mortem was proposed. Some time afterwards a second examination was made, when signs of life were detected; but it was only after the suggestion of a post mortem and a threat of the galvanic battery that she rose to her feet, nothing amiss, walked round the cell, and afterwards enjoyed her breakfast. It should be said that the hour of visit to the Dunfermline case was four A. M.; but the mistake which occurred will be useful to police surgeons generally, whose patients are often so repulsive as to render a minute examination a most disagreeable duty. No suggestion of catalepsy has been made in either case, so that the parts must have been carefully rehearsed."

— M. Thuillier, who not long ago went to Egypt as a member of Pasteur's commission to investigate cholera, died from the disease shortly after his arrival in that country. Singularly enough his was the only death from cholera reported the day it took place. He was only twenty-seven years of age, and having been for some years Pasteur's assistant in his laboratory, had been intimately connected with some of his later investigations. He had charge of the parties sent to inoculate sheep against charbon in Hungary and in Prussia.

— According to the *British Medical Journal*, which quotes from the *Journal de Ploërmel*, a curious example of one of those outbreaks of epidemic nervous

disorder which were characteristic of the Middle Ages, but are now rarely heard of, has recently been seen. Of fifty pupils of the Girls' Congregational School of Saint Marlo des Trois Fontaines, upward of thirty-five have been attacked by a nervous disorder having all the symptoms of St. Vitus' dance. The school has been closed by order of the local authorities.

NEW YORK.

— The Saturday and Sunday Hospital Association held a meeting October 15th, preparatory to the annual hospital collection for 1883. A report made by the executive committee showed that the Association had recently greatly extended its field of activity, and that the collection to be taken in the different churches and synagogues this year would probably be much the largest in the history of the Association. The report stated that there are 347 Protestant churches and chapels and 30 synagogues in the city, and out of this whole number, 377, only 97 contributed to the fund last year. The largest proportion of those joining in the movement was in the Protestant Episcopal Church, in which 49 out of 81 churches and chapels contributed. It was determined to secure if possible a more general collection among the churches this year, and accordingly nearly every clergyman in the city has been called upon by a gentleman duly authorized to represent the Association. By this method of personal appeal all the denominations have been brought more heartily into the work, and the indications of the canvass now approaching a close are that there is a probability that the number of contributing churches, chapels, and synagogues will be nearly trebled, since up to the present time 275 out of the 377 have pledged themselves to make a collection. It is hoped that eventually fully 300 will contribute. It was stated that in addition to the churches that sent their contributions to the treasurer of the Association, twenty-three churches sent their collections directly to the treasurers of various hospitals last year.

— The new wing of St. Vincent's Hospital on Twelfth Street is now completed, and in order to assist in procuring the necessary furniture and appointments for it Mr. Lawrence Barrett gave a special performance of "Richelieu" on October 18th, by which the handsome sum of nearly \$5000 was raised.

— Much opposition is being expressed by the property-holders on the Hudson to placing the new aqueduct on the shores of that river. It is claimed by them that there would be great risk of tapping the wells between the aqueduct and the Hudson River, and that sickness would be caused by the removal of the débris from the tunnel; while along the other route proposed, the Saw-Mill River route, the country is much less thickly settled, and the property of much less value. It is argued, too, that the new aqueduct should be separated as far as possible from the old (which lies along the Hudson), so that neither would be affected by an accident to the other. The question has not yet been decided by the Aqueduct Commissioners.

— The Board of Health of the town of East

Chester, in consequence of representations made to it with regard to the prevailing sickness and mortality among the infants and young children at the branch of the New York Infant Asylum near Mount Vernon, West Chester County, recently held a special meeting and appointed a committee of investigation. The committee found two cases of diphtheria and one of measles (the patients in these cases being placed in tents), and in the morgue three dead children. It was decided to require the immediate removal of the children suffering from contagious diseases to comfortable quarters, but where they could still be quarantined. A coroner's jury in the case of one of the infants that died rendered a verdict in which the institution is thus severely arraigned: "It appears to us that within a period of two months past fully thirty per cent. of the children in the asylum have died. This fearful rate of mortality, in our opinion, is the result of gross negligence upon the part of those having charge of the medical and sanitary department of the institution, and a lack of attention on the part of the president of the society, acting under the authority of the board of management, in appointing and retaining a person incompetent of performing the duty required of a physician in charge of such an institution. . . . Further, we request the coroner to call the attention of the District Attorney of this county to this investigation, and request him to inquire whether the extraordinary rate of mortality above referred to is not a proper subject for criminal investigation by the grand jury." The incompetent person referred to is a female physician who not long since was appointed at the institution to supersede Dr. Brush, a gentleman of high scientific attainments, who has given special attention to the management of infants and young children. A few months ago the management of the New York Infant Asylum, under the direction of Mr. Clark Bell, won a very unenviable notoriety by arbitrarily dismissing almost its entire medical board without cause, and now Messrs. Theodore Roosevelt and T. K. Gibbs, members of the board of managers, have sent to the Commissioners of the State Board of Charities for the County of New York a series of charges against Mr. Bell.

— In the Monmouth County (N. J.) Court Judge Walling has given a ruling which is said to affect all the local boards of health of the State of New Jersey. An individual was on trial for assaulting Sanitary Inspector Coles, of Asbury Park, while the latter was making an inspection of his property. In his charge to the jury the judge said that the Board of Health had no right to appoint an inspector, and no authority to make an inspection of any man's premises, except in cases where a complaint had been made, and that after a proper complaint had been made a majority of the Board of Health must make the inspection. On account of this opinion the jury acquitted the prisoner, and the latter announced his intention to prosecute the members of the Board of Health and Inspector Coles for false arrest and imprisonment.

— Dr. H. S. Tanner, of fasting notoriety, was arrested on October 19th at Jamestown, New York, on a charge

of not being properly registered in the County Clerk's office. He has a diploma from the "Eclectic Medical Institute," dated February 2, 1859, and indorsed by the United States Medical College of New York, which is not a legal institution. Dr. Tanner is the third eclectic physician who has been arrested in Jamestown recently on information lodged with the authorities by the secretary of the Chautauqua County Board of Censors.

— A dinner was given at the Brunswick, October 14th, by the American Chemical Society to Professor Houmanf, Professor of Chemistry, and Professor Vogel, Professor of Light and Photography in the University of Berlin, and among those present were Professors Horsford of Providence, Silliman, Johnson, and Hunt, of Yale, Doremus and Chandler, of New York, Morton and Leeds, of the Stevens Institute, Hoboken, Eggleston, of Cornell, and Booth, President of the American Chemical Society.

Miscellany.

THE CELEBRATION OF THE ONE HUNDREDTH ANNIVERSARY OF THE HARVARD MEDICAL SCHOOL, AND THE DEDICATION OF ITS NEW BUILDING.

THIS interesting occasion was observed on the 17th inst., as was recorded by the JOURNAL last week, but the lateness of the date prevented our giving an extended notice of the event in that issue.

The programme opened at eleven A. M. in Huntington Hall of the Massachusetts Institute of Technology, before a large and distinguished audience. The platform was occupied by the President and other members of the Medical Faculty and a number of invited guests, among whom were noticed Sir William MacCormac, Sir Lyon Playfair, President Gilman of Johns Hopkins University, Gen. F. A. Walker of the Institute of Technology, Drs. Fordyce Barker and Sturgis of New York, Drs. Mullin, Howard, and Campbell of Canada, Dr. Hosmer, President of the Massachusetts Medical Society, Drs. Murray and Head, U. S. A., Rev. A. P. Peabody, Hon. Martin Brimmer, Mr. Henry P. Kidder, Col. Henry Lee, Hon. Francis E. Parker, Mayor Palmer of Boston, Ex-Mayor Samuel A. Green, and others. The two emeriti professors, Drs. Holmes and Bigelow, were seated near the desk, while behind them were displayed on a tasteful background of red drapery the counterfeit presentations of the two gentlemen, that of the former on canvas and of the latter in marble, to be presented to the School as permanent and vivid reminders of the two distinguished men who had conferred so much distinction upon it. The exercises were opened with an address by President Eliot, which was as follows:—

ADDRESS OF PRESIDENT ELIOT.

We are met to celebrate the beginning of the second century of the Medical School's existence and the simultaneous completion of its new building. It is a hundred years since John Warren, Benjamin Waterhouse, and Aaron Dexter were installed as professors of anatomy and surgery, theory and practice, and materia medica respectively, and without the aid of col-

lections or hospitals began to lecture in some small rough rooms in the basement of Harvard Hall and in a part of little Holden Chapel at Cambridge. From that modest beginning the School has gradually grown until it counts a staff of forty-seven teachers,—ten professors, six assistant professors, nine instructors, thirteen clinical instructors, and nine assistants,—working in the spacious and well-equipped building which we are shortly to inspect, and commanding every means of instruction and research which laboratories, dispensaries, and hospitals can supply. Out of our present strength and abundance we look back to the founding of the School and to its slow and painful development. We bear in our hearts the three generations of teachers who have served this school with disinterested diligence and zeal. We recall their unrequited labors, their frequent anxieties and conflicts, and their unfulfilled hopes; we bring to mind the careful plantings and the tardy harvests, reaped at last, but not by them that sowed. We meet, indeed, to rejoice in present prosperity and fair prospects, but we would first salute our predecessors and think with reverence and gratitude of their toils and sacrifices, the best fruits of which our generation has inherited.

The Medical Faculty of to-day have strong grounds for satisfaction in the present state of the School, for they have made great changes in its general plan and policy, run serious risks, received hearty support from the profession and the community, and now see their efforts crowned with substantial success. By doubling the required period of study in each year of the course, instituting an admission examination, strengthening the examinations at the end of each year, and establishing a voluntary fourth year of instruction, which clearly indicates that the real standard of the Faculty cannot be reached in three years, they have taken step after step to increase their own labors, make the attainment of the degree more difficult, and diminish the resort of students to the School. They have deliberately sacrificed numbers in their determination to improve the quality of the graduates of the School. At the same time they have successfully carried out an improvement in medical education which required large expenditures. This improvement is the partial substitution, by every student, of personal practice in laboratories for work upon books and attendance at lectures. The North Grove Street building, erected in 1846-47, contained only one small laboratory for students, that of anatomy. We shall shortly see that the new building contains a students' laboratory for each of the five fundamental subjects,—anatomy, physiology, chemistry, histology, and pathology,—and that a large part of the building is devoted to these working-rooms. It was a grave question whether the profession, the community, and the young men who year by year aspire to become physicians and surgeons, would support the Faculty in making these improvements. The answer can now be recorded. The School has received by gift and bequest \$320,000 in ten years; it has secured itself in the centre of the city for many years to come by the timely purchase of a large piece of land; it has paid about \$220,000 for a spacious, durable, and well-arranged building; it has increased its annual expenditure for salaries of teachers from \$20,000 in 1871-72 to \$36,000 in 1882-83; its receipts have exceeded its expenses in every year since 1871-72, and its invested funds now exceed those of 1871 by more than \$100,000. At the same time the School has become a cen-

tre of chemical, physiological, histological, and sanitary research, as well as a place for thorough instruction; its students bring to the School a better education than ever before, they work longer and harder while in the School, and leave it prepared, so far as sound training can prepare them, to enter, not the overcrowded lower ranks of the profession, but the higher, where there is always room. The Faculty recognize that the generosity of the community and the confidence of the students impose upon them reciprocal obligations. They gladly acknowledge themselves bound to teach with candor and enthusiasm, to observe and study with diligence that they may teach always better and better, to illustrate before their students the pure scientific spirit, and to hold all their attainments and discoveries at the service of mankind. Certainly the Medical Faculty have good reason to ask to-day for the felicitations of the profession and the public.

Nevertheless, the governors, teachers, graduates, and friends of this School have no thought of resting contented with its present condition. Instructed by its past they have faith in its future. They hope, they know, that the best fruits of their labors will be reaped by later generations. The medical profession is fortunate among the learned professions in that a fresh and boundless field of unimaginable fertility spreads out before it. Its conquests to come are infinitely greater than those already achieved. The great powers of chemistry and physics, themselves all new, have only just now been effectively employed in the service of medicine and surgery. The zoölogist, entomologist, veterinarian, and sanitarian have just begun to contribute effectively to the progress of medicine. The great achievements of this century in medical science and the healing art are all prophetic. Thus, the measurable deliverance of mankind from small-pox is an earnest of deliverance from measles, scarlatina, and typhoid fever. Within forty years anæsthetics and antiseptics have quadrupled the chances of success in grave surgical operations, and have extended indefinitely the domain of warrantable surgery; but in value far beyond all the actual benefits which have thus far accrued to mankind from these discoveries is the clear prophecy they utter of greater blessing to come. A medical school must needs be always expecting new wonders.

How is medical science to be advanced? First, by the devoted labors of men, young and old, who give their lives to medical observation, research, and teaching; secondly, by the gradual aggregation in safe hands of permanent endowments for the promotion of medical science and of the sciences upon which medicine rests. Neither of these springs of progress is to fail us here. Modern society produces the devoted student of science as naturally and inevitably as mediæval society produced the monk. Enthusiastic devotion to unworldly ends has not diminished; it only manifests itself in new directions. So, too, benevolence and public spirit, when diverted by the teachings of both natural and political science from many of the ancient forms of benevolent activity, have simply found new and better modes of action.

With thankfulness for the past, with reasonable satisfaction in the present, and with joyful hope in the future, the Medical Faculty celebrate this anniversary festival, welcoming their guests, thanking their benefactors, and exchanging with their colleagues, their students, and the governing boards mutual congratula-

tions and good wishes as the school sets bravely out upon its second century.

At the conclusion of his address President Eliot introduced the orator of the day in the following words: "And now, ladies and gentlemen, I have the pleasure of presenting to you our oldest professor and our youngest; our man of science and our man of letters, our teacher and our friend, Dr. Holmes."

Dr. Holmes's address, which we published in full last week, was attentively listened to, and its many happy expressions appreciatively received by an audience which was in full *rapport* with the speaker. The vigorous defense of the conduct of the anatomical department against the charges which had been made against it in particular was warmly applauded.

PRESENTATION OF A PORTRAIT OF PROFESSOR HOLMES.

At the conclusion of the oration Dr. Francis Minot presented to the School the portrait of Dr. Holmes in these words:—

MR. PRESIDENT,—Many of the alumni of the School, together with some of its present students, have desired that a permanent memorial of their beloved teacher, Prof. Oliver Wendell Holmes, should be placed in the new college building in token of their gratitude for the great services which he has rendered to many generations of his pupils. By his eminent scientific attainments, his sound methods of teaching, his felicity of illustration, and his untiring devotion to all the duties of his chair he inspired those who were so fortunate as to come under his teaching with the importance of a thorough knowledge of anatomy, the foundation of medical science. In the name of the alumni and students of this college I have the pleasure of presenting to the Medical Faculty a portrait of Professor Holmes, painted by Mr. Alexander, to be placed in the college in remembrance of his invaluable services to Harvard University, to the medical profession, and to the community.

PRESENTATION OF A BUST OF PROFESSOR BIGELOW.

Immediately after Dr. Minot had finished his remarks, Dr. Samuel A. Green, in behalf of the donors, presented a bust of Dr. Henry J. Bigelow as follows:—

The pleasant duty has been assigned me, Mr. President, to present to you, as the head of the corporation of Harvard College, in behalf of his many friends, this animated bust of Prof. Henry J. Bigelow. The list of subscribers comprises about fifty names, and includes nearly all the surgeons of the two great hospitals in this city, several gentlemen not belonging to the medical profession, but warm personal friends of Dr. Bigelow, a few ladies who had been his patients, and all the surgical house-pupils who had ever been connected with the Massachusetts General Hospital during his long term of service at that institution, so far as they could easily be reached by personal application. The bust is given on the condition that it shall be placed permanently in the new surgical lecture room, which corresponds to the scene of Dr. Bigelow's long labors in the old building. It has been made by the eminent sculptor, Launt Thompson, of New York, and is a most faithful representation of the distinguished surgeon. It outlines with such accuracy and precision the features of his face and the pose of his head that nothing is wanted, in the opinion of his friends, to make it a correct likeness.

I need not, in the presence of this audience, name the various steps by which Dr. Bigelow has reached the high position which is conceded to him as freely and fully in Europe as it is in America, but I cannot forbear an allusion to some of his original researches. His mechanism of the reduction of a dislocated femur by manipulation was a great discovery in surgical science, and follows as a simple corollary to the anatomical facts which he has so clearly and minutely demonstrated. His operation of rapid lithotomy has deprived a painful disease of much of its terror as well as of its danger. Nor should I overlook on this occasion his quick and ready discernment of the importance of Dr. Morton's demonstration of the use of ether as a safe anæsthetic, which took place at the Massachusetts General Hospital in the autumn of 1846. The discovery of this greatest boon to the human family, since the invention of printing, was fraught with such immense possibilities that the world was slow to realize its magnitude; but by the clear foresight and prudent zeal of Dr. Bigelow, shown in many ways, the day was hastened when its use became well-nigh universal.

Dr. Bigelow has filled the chair of surgery in the Harvard Medical School during thirty-three years, a period of professional instruction that rarely falls to the lot of any teacher; and he now leaves it with the honored title of Professor Emeritus. During this long term of service he has taught, through his lectures, probably not fewer than 1800 students, who have graduated at the School, and perhaps 7500 more who have taken their degrees elsewhere; and by these thousands of physicians now scattered throughout the land, those of them who survive, Dr. Bigelow is remembered as most eminently a practical teacher. Active in his profession, clear in his instruction, and enthusiastic in his investigations, he always had the happy faculty of imparting to his students a kindred spirit and zeal. *Haud inexpertus loquor.*

President Eliot then briefly accepted the portrait and the bust in behalf of the Medical School, as memorials of two great teachers, saying that it was such instructors, after all, and not great buildings, that were the glory and pride of an institution of learning.

AT THE NEW BUILDING.

This closed the exercises at Huntington Hall, and an adjournment was then made to the new building at the corner of Boylston and Exeter Streets, where the formal services of dedication took place. This building has already been described at length in this journal, and it only remains to say that the day of dedication found everything in perfect order, and that an abundant corps of ushers were in attendance to show visitors every part of the edifice. As soon as the company was assembled in the main hall and the galleries surrounding it, it was called to order by President Eliot, when a prayer of dedication was offered by Rev. A. P. Peabody, D. D. This and the following exercises occurred on the grand staircase, where they could be well heard and witnessed throughout the building.

President Eliot then said: "In behalf of the President and Fellows of Harvard University and of the Medical Faculty, I now declare this building to be devoted to medical science and the advancement of the art of healing."

Dr. H. W. Williams then spoke in behalf of the Medical Faculty as follows:—

FRIENDS OF THE HARVARD MEDICAL SCHOOL,—For a hundred years the Medical Faculty of Harvard College have earnestly sought to discover, and striven faithfully to teach, whatever might exalt the condition, relieve the woes, and prolong the service of those minds and bodies through which man lives, and moves, and is. Year by year they have seen their horizon of knowledge extended and their sphere of duty enlarged. But, though zeal and self-sacrifice have not been wanting, their efforts to be useful have been continually hindered because of imperfect facilities and scanty resources.

All is changed! In this more wonderful than Aladdin's palace, risen from the sea,¹ and which has already endured the wrath and mercy of the flames, we see a fulfillment of our hopes, and the means and assurance of success. Thanks to generous benefactors, there will no longer be a lack of room or of appliances for our needs; our work will go on under fairer auspices, and we can offer to disciples of the healing art fitter opportunities and ampler aid in their studies.

As spokesman of the Faculty, on this occasion so full of felicitation and of promise, I would I could give to their message a host of tongues, to adequately thank those whose great flood of bounty has thus favored and endowed us. In occupying this beautiful and convenient structure we shall ever feel that the place is dignified by the givers' deed. And we rejoice the more because we know that this gift of three hundred thousand dollars has been bestowed by those who are accustomed to use their own eyes in the estimation of desert; and that it signifies a hearty approval of our endeavors, and an intent that medical science, as it is to be here embodied and taught, shall have a warm and generous support.

In accepting this more than princely gift, as a token that the value and necessity of well-educated physicians, to every community, is felt and acknowledged, we hail the privilege of goodly fellowship, in which the donors and ourselves have become co-workers, to the end that blessings to the whole land may arise and be memorized in this institution; and we trust that the efforts of the Faculty to advance the knowledge, train the judgment, and perfect the skill of those entering our profession, will ever continue to deserve countenance and help.

Col. Henry Lee, in behalf of the subscribers to the building fund, then spoke as follows:—

MR. PRESIDENT,—Thanks for your invitation to be present on this interesting occasion,—the hundredth anniversary of your, Medical School, and the dedication of a new building, of fair proportions, well adapted to your wants, as far as a non-professional can judge.

You have assigned to me the honorable task of speaking for the contributors to the building fund.

I little thought, as I used to gaze with awe at that prim, solitary, impenetrable little building in Mason Street, and with the aid of imaginative companions, conjured up the mysteries within, that I should ever dare to enter and explore its interior; nor have I yet acquired that relish for morbid specimens which characterized my lamented kinsman, who devoted so many years to accumulating and illustrating your pathological collection.

It is an ordeal to a layman, Mr. President, especially to one who has reached the sixth age, to be so forcibly reminded, as one is here, of the

¹ The site occupied by the Medical College was once covered by the tides.

"last scene of all
That ends this strange, eventful history,
Sans teeth, sans eyes, sans taste, sans everything,"

and it is a further ordeal to assume to speak for others, whose motives for aiding you I may not adequately set forth.

This I can say, that we are citizens of no mean city; that private frugality and public liberality have distinguished the inhabitants of this "Old Town of Boston," from the days of the good and wise John Winthrop, whose own substance was consumed in founding this colony, to the present time.

Down through these two centuries and a half the multiform and ever-increasing needs of the community have been discovered and supplied, not by government, but by patriotic citizens, who have given of their time and substance to promote the common weal, remembering "that the body is not one member, but many, and that the members should have the same care one for another."

It is this public spirit, manifested in its heroic form in our Civil War, that has made this dear old Commonwealth what we all know it to be, despite foul slanders. Far distant be the day when this sense of brotherhood shall be lost.

Purple and fine linen are well, if one can afford them; but let not Dives forget Lazarus at his gate.

"Ill fares the land, to hastening ills a prey,
Where wealth accumulates, and men decay."

Whatever doubts may arise as to some of our benevolent schemes, our safety and progress rest upon the advancement of sound learning, and we feel assured that the increased facilities furnished by this ample building for acquiring and disseminating knowledge of our fearful and wonderful frame, will be improved by your brethren.

Some of the papers read before the International Medical Congress in London, two years ago, impressed me deeply with the many wants of the profession.

And who are more likely to have their wants supplied? for the physician is not regarded here, as in some countries, as the successor to the barber surgeon, and his fees slipped into his upturned palm as if he were a mendicant or a menial.

Dining with two Englishmen, one an Oxford professor, the other the brother of a lord, a few years since, I was surprised to hear their views of the social standing of the medical profession, and could not help contrasting their position here, where, if not all autocrats, they are all constitutional, and some of them hereditary, monarchs, accompanied by honor, love, obedience, troops of friends.

But, however ranked, physicians have the same attributes the world over. I have had occasion to see a good deal of English, French, German, and Italian physicians under very trying circumstances, and have been touched by their affectionate devotion to their patients.

The good physician is our earliest and our latest friend; he listens for our first and our last breath; in all times of bodily distress and danger we look up to him to relieve us.

Neither "the pestilence that walketh in darkness; nor the sickness that destroyeth in the noonday," deters him.

"Alike to him is time, or tide,
December's snow, or July's pride;
Alike to him is tide, or time,
Moonless midnight, or matin prime."

The faithful pursuit of any profession involves sacrifice of self; but the man who calls no hour his own, who consecrates his days and nights to suffering humanity, treads close in the footsteps of his Master.

No wonder, then, that the bond between them and their patients is so strong; no wonder that we respond cheerfully to their call, in gratitude for what they have, and in sorrow for what they have not, been able to do, to preserve the lives and to promote the health of those dear to us. And how could money be spent more economically than to promote the further enlightenment of the medical profession? What better legacy can we leave our children, and our children's children, than an illumined Medical Faculty?

Following the remarks of Colonel Lee, Dr. H. P. Bowditch, the dean of the Faculty, briefly expressed their acceptance of the trust and responsibilities imposed upon them, and closed with an invitation to inspect the building and to partake of refreshments which were served in the medical lecture rooms.

The distinguished strangers from other cities were entertained at dinner in the evening by various members of the profession in Boston, and subsequently a reception was held at Young's Hotel by the Faculty of the Harvard Medical School, which was very numerous attended, and was an extremely enjoyable occasion. The company separated about half-past eleven o'clock, after the discussion of an elaborate and excellent supper.

Among the guests from other cities who were present during the day may be mentioned Presidents Gilman, of the Johns Hopkins University; Laws, University of Missouri; Robinson, Brown University; Colonels Murray and Head, surgeons United States Army; Sir William MacCormac and Sir Lyon Playfair, of London; Professors Osler, Campbell, Howard, T. Sterry Hunt, Montreal; Drs. Barker, Agnew, Sims, Dalton, W. H. Draper, Satterthwaite, Shradly, C. C. Lee, of New York; Drs. H. C. Wood, Tyson, Hays, Woodbury, Mears, of Philadelphia; Dr. Twitchell, of Keene, N. H.; Drs. Gerrish, Wood, and Dana, of Portland, Me.; Drs. Caswell, Parsons, Miller, and Ely, of Providence, R. I.

MATERIAL WANTED FOR EMBRYOLOGICAL RESEARCH.

THOSE of our readers who obtain embryos in the course of their practice, which they do not require for their own use, will confer a special and valuable favor upon Dr. Charles S. Minot by sending them to him at the Harvard Medical School, on Boylston Street. Dr. Minot has undertaken an extended investigation for the purpose of completing a general work on human embryology, and he is therefore very desirous of obtaining the largest material possible of all the stages of development, the latest as well as the earliest. He will gladly bear any expenses incurred in sending the desired specimens, all of which will be immediately and gratefully acknowledged. It is very advantageous to have the fetus in as fresh a condition as possible, otherwise it may be best preserved in ordinary alcohol weakened with one sixth water; but an embryo should not remain in this fluid more than four days, when it should, to assure preservation, be transferred to ordinary strong alcohol. It is only by the generous assistance of practicing physicians that such studies as those above alluded to can be carried out successfully.

REPORTED MORTALITY FOR THE WEEK ENDING OCTOBER 13, 1883.

Deaths reported 2174 (no reports from Brooklyn and New Orleans): under five years of age, 796: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 444, consumption 299, lung diseases 190, diarrhoeal diseases 138, diphtheria and croup 112, typhoid fever 77, scarlet fever 34, malarial fevers 33, whooping-cough 14, cerebro-spinal meningitis 11, erysipelas nine, puerperal fever eight, measles seven, small-pox one. From *scarlet fever*, Philadelphia 10, Boston seven, Buffalo four, Chicago and Cincinnati three each, New York and Lowell two each, St. Louis, Baltimore, and Pittsburg one each. From *malarial fevers*, New York 10, St. Louis eight, Philadelphia six, Baltimore four, Charleston three, Chicago and Providence one each. From *whooping-cough*, New York four, District of Columbia three, Chicago, Baltimore, and Pittsburg two each, Springfield one. From *cerebro-spinal meningitis*, New York six, Philadelphia, Boston, Providence, Nashville, Fall River one each. From *erysipelas*, New York six, Philadelphia, Chicago, and St. Louis one each. From *puerperal fever*, Chicago two, New York, Boston, St. Louis, Providence, Lowell, and Somerville one each. From *measles*, New York five, Baltimore and District of Columbia one each. From *small-pox*, Philadelphia one.

In the 37 cities and towns of Massachusetts, with an estimated population of 1,130,974 (estimated population of the State 1,922,530), the total death-rate for the week was 18.53 against 20.08 and 17.62 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending September 29th, the death-rate was 19.1. Deaths reported 3154: diarrhoea

279, acute diseases of the respiratory organs (London) 163, scarlet fever 102, fever 35, measles 49, whooping-cough 44, diphtheria 26, small-pox (Birmingham four, London and Sunderland two each) eight. The death-rates ranged from 14.1 in Leicester to 33.2 in Newcastle-on-Tyne; Bristol 15.4; Bradford 15.8; London 16.6; Wolverhampton 18.2; Leeds 19; Birmingham 20.1; Sheffield 21.9; Manchester 25.1; Liverpool 26.1; Preston 28.6. In Edinburgh 18.8; Glasgow 22.3; Dublin 23.7.

For the week ending September 22d, in 168 German cities and towns, with an estimated population of 8,688,139, the death-rate was 23.5. Deaths reported 3920; under five years of age, 2061; consumption 455, diarrhoeal diseases 281, lung diseases 255, diphtheria and croup 213, scarlet fever 87, typhoid fever 73, whooping-cough 66, measles and röteln 36, puerperal fever 20, small-pox (Gross-Glogau one) one. The death-rates ranged from 11.1 in Darmstadt to 33.8 in Magdeburg; Königsberg 33.5; Breslau 30.7; Munich 26.9; Dresden 21.8; Berlin 27; Leipzig 20.8; Hamburg 23.6; Cologne 23.8; Frankfurt a. M. 12; Strasburg 18.2.

For the week ending September 29th, in the Swiss towns, there were 34 deaths from diarrhoeal diseases, consumption 19, lung diseases three, diphtheria and croup three, scarlet fever one, whooping-cough one, erysipelas one, typhoid fever one. The death-rates were, at Geneva 14.3, Zurich 10, Basle 16.7; Berne 20.3.

The meteorological record for the week ending October 13th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

Date.	Barom-eter.	Thermom-eter.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM OCTOBER 12, 1883, TO OCTOBER 19, 1883.

HARTSUFF, ALBERT, major and surgeon. Granted leave of absence for fifteen days. Paragraph 2, S. O. 205, Department of the Missouri, October 6, 1883.

HUNTINGTON, DAVID L., major and surgeon. By direction of the President will, until further orders, take charge of the office of the Surgeon-General of the Army and perform the duties pertaining thereto. Paragraph 3, S. O. 234, A. G. O., October 11, 1883.

MEACHAM, FRANK, major and surgeon. Assigned to duty at Fort Douglas, Utah. Paragraph 3, S. O. 109, Department of the Platte, October 6, 1883.

STERNBERG, GEORGE M., major and surgeon. Granted leave of absence for one month, to date from October 6, 1883, with permission to go beyond the limits of the Department, and to apply for extension of one month. Paragraph 3, S. O. 134, Department of California, October 4, 1883.

TAYLOR, MORSE K., major and surgeon. Assigned to duty at Fort Sill, I. T. Paragraph 4, S. O. 210, Department of the Missouri, October 13, 1883.

CRONKHITE, H. M., captain and assistant surgeon. Assigned to duty at Fort D. A. Russell, Wyoming. Paragraph 3, S. O. 109, Department of the Platte, October 6, 1883.

HEIZMANN, CHARLES L., captain and assistant surgeon. Granted leave of absence for six months, with permission to go beyond sea. Paragraph 3, S. O. 235, A. G. O., October 15, 1883.

WEISSEL, DANIEL, captain and assistant surgeon. Assigned to duty at Fort Fred Steele, Wyoming. Paragraph 3, S. O. 109, Department of the Platte, October 6, 1883.

ARTHUR, W. H., first lieutenant and assistant surgeon. Assigned to duty at Fort Douglas, Utah. Paragraph 3, S. O. 109, Department of the Platte, October 6, 1883.

STRONG, NORTON, first lieutenant and assistant surgeon. Assigned to duty at Fort Washakie, Wyoming. Paragraph 3, S. O. 109, Department of the Platte, October 6, 1883.]

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING WEEK ENDING OCTOBER 20, 1883.

HORN, W. T., medical director, and **CLEBORNE, C. J.**, medical inspector, ordered to the U. S. S. Hartford at Panama, on duty connected with a court martial.

GORGAS, A. C., medical inspector, detached from Naval Hospital, Chelsea, Mass., November 10th, and ordered to the Naval Hospital, Mare Island, Cal.

BROWNE, J. M., medical director, ordered as a member of the National Board of Health.

HEFFINGER, A. C., passed assistant surgeon, ordered to temporary duty at Navy Yard, Portsmouth, N. H.

WHITING, ROBERT, passed assistant surgeon, granted leave of absence for three months.

The orders in last week's report of Surgeon W. J. SIMON and Passed Assistant Surgeon M. H. CRAWFORD should read to U. S. S. Shenandoah instead of Trenton.

OBITUARY.

ROBERT W. OLIPHANT, M. D., son of the late Rev. David Oliphant, of Beverly, Mass., died in St. Louis, Mo., on the 9th inst., aged fifty-eight years. He graduated at Amherst, took his medical degree at Harvard, and, in 1848, settled in St. Louis. He devoted himself closely to his profession, and acquired a large and lucrative practice. One of the oldest members of the Massachusetts colony in that city, he had many friends to whom he ever extended a cordial hospitality. He leaves a widow and one daughter.

SUFFOLK DISTRICT MEDICAL SOCIETY.—There will be a stated meeting of the Society on Saturday, October 27th, at 19 Boylston Place, at 7.45 P. M. Paper by Dr. Charles Harrington: Sub-Soil Water as a Factor in the Causation of Outbreaks of Typhoid Fever. The discussion will be opened by Drs. Walcott, Durgin, and Prince. Choice of Nominating Committee. Supper after the meeting. H. C. HAVEN, Secretary.

BOOKS AND PAMPHLETS RECEIVED.—On Malpositions of the Kidney. Thesis for the Degree of M. D. By David Newman, M. B. C. M. D. (Reprint from Glasgow Medical Journal.) Recherches Cliniques et Thérapeutiques sur l'Epilepsie, l'Hystérie, et l'Idiotie. Compte Rendu du Service des Epileptiques et des Enfants Idiots et Arriérés de Bicêtre Pendant l'Année 1881. Par Bourneville, Bonnaire, et Wuillamie. Publications du Progrès Médical. Paris. 1882.

Guiteau. A Case of Alleged Moral Insanity. A Rejoinder by J. J. Elwell to Reply of E. C. Spitzka, M. D., New York. Second Paper. (Reprint.) 1883.

Sea-Sickness; its Cause, Nature, and Prevention, without Medicine or Change in Diet. A Scientific and Practical Solution of the Problem. By William H. Hudson. Boston: S. E. Cassino & Co. 1883.

Medical Education and the Regulation of the Practice of Medicine in the United States and Canada. Illinois State Board of Health. 1883.

The Endoscope in Disease of the Male Urethra. By A. Ravogli, M. D., Cincinnati, Ohio. (Reprint from Cincinnati Lancet and Clinic.)

The Mental Status of Guiteau. A Review. By James H. McBride, Superintendent of Hospital for Insane at Milwaukee, Wis. (Reprint.) 1883.

The Collective Investigation of Diphtheria as conducted by the Therapeutic Gazette, Detroit, Mich. With Editorial Summary. By J. J. Mulheron, M. D. Detroit, Mich.: George S. Davis. 1883.

Women as a Physician. Illustrious Examples drawn from History, etc. By Eugene F. Cordell, M. D. Abstract of an Introductory Lecture before the Woman's Medical College of Baltimore, October 1, 1883. (Reprint.)

Clinical Report on Cases of Lacerated Cervix and Ovariectomy from Private Practice. By Joseph H. Warren, A. M., M. D. Boston, Mass. (Reprint.) 1883.

Lectures.

CLINICAL LECTURE.¹

DELIVERED AT BELLEVUE HOSPITAL, NEW YORK,
MAY 25, 1883.

BY PROF. AUSTIN FLINT, M. D.

I. HEART COMPLICATION IN ACUTE ARTICULAR RHEUMATISM.

GENTLEMEN, — The young man whom I bring before you first to-day is now convalescing from an attack of acute articular rheumatism, which began three weeks ago. He entered the hospital only a few days since, however, and up to that time he had received no medical treatment. At the time that he was admitted different joints of the body were affected, and there was still a certain amount of fever present; but under the treatment adopted here the symptoms soon disappeared. This consisted of twenty grains each of the bicarbonate of sodium and salicylate of sodium every two hours. The system was thus promptly brought under the influence of these remedies, and it seems to have tolerated this large amount very well.

The special point to which I wish to direct your attention in connection with this case is that an examination of the heart reveals the presence of a mitral systolic murmur. The question at once arises, Is this murmur the result of lesions caused by the attack of acute rheumatism from which the patient is just recovering? You must recollect, in the first place, that endocarditis not infrequently entirely escapes notice. In this instance the patient informs me that he has had no pain in the cardiac region; but even if he had had pain there, it might very likely have been due to other causes, such as neuralgia or muscular trouble. While endocarditis in many instances does not give rise to any pain, it is also true of it, as well, that it may not occasion any disturbances of the heart's action, or much increase in the fever due to the attack of acute rheumatism in connection with which it occurs. In a great many cases we can only tell that endocarditis has supervened by the fact that an organic murmur is discovered which did not previously exist. If there has been any increase in fever noted, this would, of course, be corroborative evidence of the existence of endocarditis. As I have examined the present patient for the first time to-day, I cannot say whether the murmur of which I have spoken is due to a recent endocarditis or to one occurring in connection with some previous attack of acute rheumatism. On questioning him I find that he has had previous attacks of the latter; the first one having occurred ten years ago, and the last one, four years ago. There is one point, however, which may throw light on the matter. If there is enlargement of the heart, there can be no doubt that the mitral murmur results from an old lesion; while if there is no enlargement, the inference is that the endocarditis has occurred during the recent attack of rheumatism, although this does not necessarily follow. Before proceeding to find out the area of cardiac dullness here, I may premise that the patient tells me that he has sometimes suffered from shortness of breath on exercise, which would seem to indicate the existence of more or less cardiac trouble prior to this illness. Now making the examination, I find

that the apex beat is in its normal position, and careful percussion fails to elicit any increase in the normal limits of cardiac dullness. It cannot be positively determined, therefore, whether the endocarditis occurred in connection with the recent, or some previous, attack of rheumatism. We can only say that if it did take place during some other attack, lesions have not as yet resulted which commonly give rise to cardiac enlargement.

It may perhaps be asked whether this may not be merely a functional murmur, after all. I think it is not, because it has been doubted whether a persistent mitral murmur is ever of this character; and even if such a thing were possible, it must be of such rare occurrence as to make it scarcely worth while to take the supposition into consideration. The murmur found here, it seems to me, is probably due to a little roughness of the valves resulting from endocarditis; and the lesion, whatever its nature, is at all events giving rise to no difficulty whatever at the present time. There is also, I find, a murmur at the base of the heart in this case; but this I judge to be inorganic, as it is of the character which we frequently meet with in anæmic subjects, and especially among women.

Our second patient to-day is a woman, who is still confined to her bed. She had one attack of acute articular rheumatism a year ago, and the present one commenced two weeks since, although she was not admitted into the hospital until the day before yesterday. Different joints have been affected, and she has had a certain amount of fever; but I do not know what kind of treatment she has been getting. When I first saw her, which was the day of her admission, I listened to her heart to see if I could discover the presence of a mitral murmur, and failed to detect any. I did not make any examination of the patient yesterday; but to-day I find that there is a mitral murmur. It is a direct systolic murmur, and there is no regurgitation. Unless I overlooked its presence when I examined the patient the day before yesterday, it is, therefore, a murmur which has just been developed from the effects of endocarditis. The woman says, on being questioned, that she has some præcordial pain, but it is quite evident that she lays very little stress upon it. It is a fact worthy of notice in connection with this endocarditis, that the joint symptoms have almost entirely disappeared since it commenced. On admission this patient was put upon the same treatment as the first one; but the stomach soon rebelled, and troublesome vomiting ensued. She has practically, therefore, had no treatment since she came in. The one great object of medication in acute rheumatism is to prevent cardiac complications. Although pericarditis may be accompanied by more or less danger, endocarditis is of itself of no consequence whatever. In a certain proportion of cases, however, organic lesions will sooner or later result from it; and so when I bring cases of valvular disease of the heart before you and ask whether the patients have ever had acute articular rheumatism, in nine cases out of ten the answer is an affirmative one. The question then arises, What are we to do to avoid this complication? This cannot be accomplished by cutting short the attack of rheumatism by such remedies as the salicylate of sodium; although this is certainly a very desirable thing to do. The only means at our disposal, which, so far as I know, offers any chance of warding off cardiac complications, is to render the blood alkaline as rapidly as possible,

¹ Reported for the Boston Medical and Surgical Journal.

and then keep it constantly in this condition. Reliable statistics establish the fact that this unquestionably has the effect of preventing endocarditis in a considerable proportion of cases. From half a drachm to a drachm of bicarbonate of sodium should be given every two or three hours until the urine is distinctly alkaline; after which the quantity may be greatly reduced, as a comparatively small amount is then sufficient to maintain the alkalinity. At present the patient before you is getting along very fairly, but I think that in her case it would be highly desirable to return to the alkaline treatment just as soon as it is practicable.

II. A CASE OF FATTY LIVER IN CONNECTION WITH ASCITES FROM HEPATIC CIRRHOSIS; REMARKS ON TAPPING IN THE LATTER CONDITION.

The woman who is now before you I selected the day before yesterday as a suitable case upon which to make some remarks before you in regard to the practical treatment of ascites from cirrhosis of the liver. Since then she has had a violent attack of delirium tremens, which of itself is an excellent commentary on the usual causation of this affection; but which, as you see, has left her in a condition which renders any satisfactory examination of the abdomen out of the question at present. It has been my experience that women with delirium tremens are less manageable than men suffering from it; and this patient has proved no exception to the rule, as I learn that she has made frequent attempts to assault her attendants.

The history of the case is as follows: Catherine S., fifty years of age, and a native of England. She was admitted to the hospital twelve days ago, when she stated that she had been a moderate drinker for a number of years, and that during the last six months she had been drinking hard. She would always take whiskey before breakfast, and after a time she began to suffer from vomiting of mucus in the morning, with anorexia. I may here remark that gastritis such as is thus described is rare except in connection with conditions of alcoholism, like that which is present in this case. During the last year she has vomited blood at times, and there can be little doubt that this hæmorrhage is due to cirrhosis of the liver, of which, as you know, it is one of the symptoms. She has also suffered from pain and swelling in the abdomen, and for three weeks before admission (during which time she was drinking harder than ever) she had a constant diarrhoea. Here, then, is a group of symptoms altogether characteristic of cirrhosis of the liver: ascites, hæmorrhage, and diarrhoea.

The patient has also had more or less icterus of late. The explanation of this probably is, that having a gastritis or a gastro-duodenitis jaundice has been caused either by obstruction to the passage of bile or extension of the inflammatory action along the duct. Cirrhosis of the liver, as a rule, does not give rise to icterus. The urine, which is of a specific gravity of 1014, contains bile, and also a moderate amount of albumen. The liver in this case is enlarged, and not contracted, as is usually found in cirrhosis, and I think there is good reason, therefore, to believe that there is fatty degeneration as well as cirrhosis of the liver here. The spleen is found to be enlarged, and this is corroborative evidence of the existence of cirrhosis; enlargement of the spleen being one of the ordinary concomitants of that condition.

This case, then, is one of considerable interest, first,

on account of the occurrence of delirium tremens, and, secondly, on account of the ascites. The delirium tremens has been treated with a moderate quantity of alcohol, the bromides, and, I believe, a certain amount of opium. The violent symptoms have disappeared, but you will observe that the tremor characteristic of the affection is still marked. I will not dwell upon this feature of the case; but will pass on to the ascites, which is the topic of which I wish to speak more particularly. There is one point in connection with the treatment of this condition which I have inculcated for the last twenty years, namely, the advantage of early tapping, and of tapping frequently afterwards, if necessary; and although I have done this with all the earnestness in my power, I find that both in this country and in Europe the great mass of the profession still adopt this measure only as a last resource, when everything else has failed, and the danger to life becomes imminent from the enormous accumulation of fluid. It is only recently that I saw in the *British Medical Journal* the report of a discussion on this subject in London, in which the majority of those who spoke took this view. I have generally observed that when ascites comes on in connection with cirrhosis of the liver the quantity of fluid increases quite rapidly. The rule by which I am always governed, and which I cannot recommend to you too strongly, is this, that the moment that the accumulation becomes at all inconvenient to the patient, tapping should forthwith be performed.

The principal objections that have been urged against this plan are two in number: first, the danger of collapse if the patient is in a weak state; and, secondly, the danger of peritonitis. In regard to the first, I may say that in all my experience I have not only never seen a fatal result, but have never met with a case in which there was any alarming syncope. If dangerous syncope is apprehended, however, all risk of it can be avoided by resorting to aspiration, by means of which the fluid is removed very slowly. As to peritonitis, I have known but one instance in which this resulted from puncture of the abdomen, and this was in a case complicated with general dropsy which was caused by disease of the kidney. In renal disease, as is well known, there is a direct tendency to inflammation of the serous membranes. But even in that case peritonitis would probably have been avoided if aspiration had been employed. I usually use an ordinary trocar and canula; but the only objection that I have to aspiration is the length of time which it requires for its performance. It seems to me, therefore, that there is no weight whatever in the objections which have been made to early and repeated tapping. The remedies employed to get rid of the fluid when this is not resorted to are of three kinds: diaphoretics, diuretics, and hydrogogue cathartics. Very little reliance is ever placed in the first two of these, which are very slow and uncertain in their effects, and the chief dependence is on the third class of agents. This is more efficient, it is true, but at the same time it must be acknowledged that the action of such remedies is very depressing, and, consequently, detrimental to the general health of the patient. If, therefore, it is desirable to get rid of the fluid in the peritonæum, why not do this at once by a trifling operation which is harmless, and prompt and efficient in its action. This, it seems to me, is the view that common sense teaches us to take of the matter.

Yesterday I saw a patient whose case has been of

great interest. I was first called to see him eleven years ago, when he was forty-five years of age. Without going into any details of the case, I will simply mention that he was suffering from ascites, and, in addition, was so reduced by vomiting and the discharge of blood from the bowels that he was considered in imminent danger. Three eminent physicians were in attendance, and although the distress caused by the abdominal fluid was very great, it was decided that it would be too much of a risk to resort to tapping. At the request of the gentleman's wife I was called in consultation, and at my suggestion the tapping was made, although I did not expect anything more than temporary relief. This was certainly afforded, and during the next three months he was tapped no less than ten times, 350 pounds of fluid being removed. After the tenth tapping there occurred a moderate accumulation; but this gradually disappeared spontaneously, and to-day the patient is in good health. I might mention many other cases in which repeated tapping was attended with the happiest results; but will not take up more of your time.

SOME REMARKS UPON INFANTICIDE, WITH REPORT OF A CASE OF INFANTICIDE BY DROWNING.¹

BY J. G. PINKHAM, M. D., MEDICAL EXAMINER.

THE crime of infanticide appears to be relatively a very frequent one in Massachusetts. The following figures taken from the statistical reports annually published with our Transactions will substantiate this statement:—

Years.	Deaths reported as by Criminal Violence.	Deaths reported as by Infanticide.	Percentage of Deaths by Infanticide.
1878	80	2	6.6+
1879	21	7	33.8+
1880	17	7	41.1+
1881	13	2	15.8+
1882	23	11	47.8+
Total . .	104	29	27.8+

These figures are derived from the reports of individual cases alone, and represent, probably, less than one third the work of medical examiners throughout the State. But if the statistics were complete there is no reason to suppose that the percentage of cases of infanticide would be shown to be any less. It is safe to say that more than one quarter part of the cases of criminal violence that come under our official notice are those of infanticide. Yet prosecutions for the offense are very rare, and convictions still rarer. In a large number of cases the medical evidence that a crime has been committed is conclusive, and yet but little effort, or none at all, is made to bring the offenders to justice. The indifference of the community to this shocking crime is surprising. Let an adult or a

child of larger growth be murdered, and an intense excitement is at once aroused. But if the victim be a helpless infant the utmost apathy prevails regarding the crime,—often sympathy for the criminal even in those cases, unhappily, not rare, in which the hand of a mother performs the cruel act. Many of you may recall the notorious case, so much talked about in the newspapers, of Lizzie Corcoran, who drowned her illegitimate child, a few days old, by throwing it into the dock at Lynn. The chain of evidence was complete, and, in fact, the crime was ultimately confessed, yet the case was never even tried, and the culprit got off scot-free.

The popular sentiment which places a low value upon infant life is in exact accord with that which looks upon pre-natal life as of no value whatever, and refuses to regard its destruction as a moral offense. It is probable that infanticide is made to appear more frequent of late than formerly by the operation of the law of medical examiners. Under the old system when the dead body of an infant was found it was usually viewed and ordered to be buried, no attempt being made to ascertain by an autopsy the cause of death. But the medical examiner, when called to view the body of an infant that appears to be in such a stage of development as to warrant the conclusion that it was viable, has but one course to pursue in the discharge of his duty, and that is to make an autopsy, and ascertain definitely whether the child were born alive or not, and if it were to determine the cause of death. The very fact that the body was cast out unburied is proof presumptive of violence, and compels this course of action. The medical examiner is not justified, under any circumstances, in regarding the life of the newly-born child as being of less consequence than that of an adult. In view of the great prevalence of infanticide it is, perhaps, incumbent upon us to give increased thought to a study of this crime in its medico-legal aspects. The work of the Society has been well begun by Dr. Abbott in his article on the Evidence of Still-birth, published in vol. i., No. 2, of our Transactions. A series of papers following it upon the various causes of death, natural and violent, in new-born children, including reports of cases, might be of great interest and value. As a slight contribution to the study of the subject I herewith report a case of infanticide by drowning.

On the 20th of December, 1882, shortly before noon, I was notified that the dead body of an infant had been found in a privy vault in the outskirts of the town. On my way to the place I met the city marshal, who told me that he had removed the child from the vault, and was then taking it to the police station. He said also that an Irish servant girl, the supposed mother of the child, required medical attendance, and requested me to go on and render it. On my arrival at the house a few minutes later I found the girl sitting by the stove in the kitchen. Having put her to bed (she walked up stairs without difficulty), I delivered her of the placenta and membranes, which were lying loose in the vagina. The perinæum had been torn through nearly to the verge of the anus. On being questioned the girl said that she was unmarried; that she had left Ireland eight months previously, having become pregnant before she started; that since her arrival in this country she had been at domestic service, and had not informed any one of her condition; that when labor pains came on she excused her-

¹ Read before the Massachusetts Medico-Legal Society at the annual meeting, June 12, 1883.

self from work by saying that she was ill, and went into the cellar, where the child was born at about nine o'clock; that shortly before the birth she had a desire to go to stool, and attempted to use a floor pail for that purpose; that the child was then born into the pail, and that she, thinking it was dead, carried it out, and threw it into the vault; that she then returned to the cellar, and washed the pail and the floor. At this point the affair was discovered by the family, who had watched her movements with some curiosity and suspicion.

The view of the body was held at the police station at three P. M. of the same day, and the autopsy soon after. The body was found lying in a small box upon a piece of newspaper which appeared to be quite wet with some clear liquid. On taking the body up to place it upon a table a considerable quantity of watery froth ran from the nose and mouth. The following are the essential facts in the record of the autopsy:—

External examination. Body that of an apparently mature male infant recently born. Length 51.4 centimetres; weight 3670 grammes. Surface mostly clean, but presenting *vernix caseosa* in the usual places, and a few bloody patches. Skin red and firm. Head large, dark, with small *caput succedaneum*. Face congested. Eyes closed. Scalp covered with hair. Mouth open. Watery froth issuing from nose and mouth. Nails well developed. Testicles in scrotum. Umbilical cord fresh and bloodless, fourteen inches in length; end ragged. Two and one half inches from the end the cord is half cut or torn through. Meconium about anus. Abdomen distended. Chest full. Slight rigor mortis. Surface cold.

Internal examination. Section along median line. Diaphragm at level of sixth rib. Liver deeply congested. Both lungs expanded, completely filling the pleural cavities; light pink in color; somewhat congested. The trachea was ligated, and the lungs together with the heart and thymus gland removed. The whole mass floated in water high above surface. Lungs floated in sections. A slightly pinkish froth exuded from both lungs on section and pressure in abundance. The trachea and large bronchi were filled with this froth. Large veins distended with blood. Blood fluid; no clots anywhere. Meconium in large intestines. Small intestines distended with gas. In the stomach was a small amount of liquid, like water. Bladder contained urine normal in appearance. Other organs, so far as examined, were healthy in appearance.

The conclusions derived from the examination were:—

- (1.) That the child was mature.
- (2.) That it had been born alive a few hours before the autopsy.
- (3.) That the cause of death was drowning.

The conclusions in regard to the maturity of the child and the time of the birth were established by the testimony of the mother as well as by the appearance presented by the body. If the mother left Ireland eight months previous to her confinement, and had then been pregnant long enough to become aware of it, she must have been at time when the birth took place. It needs no argument to show that the child was born alive. The complete expansion of the lungs makes it certain that respiration was performed after the entire extrusion of the child from the body of the mother, and that therefore the child was born alive in the English sense. It can hardly be disputed, also, that the cause of death

was drowning. No other theory would account for the presence of so large an amount of liquid and froth in the respiratory passages. This condition of things could only have been brought about by attempts to breathe under water. It is not to be expected that the signs of drowning in the case of new-born children will be precisely the same always as in case of adults. Those external appearances due directly to the submergence of the body are very likely to be absent. If Caspar's theory that the *cutis anserina* is due to mental shock is true, we should certainly never observe that. Neither should we expect so much pallor after a moderately long submergence; for the natural baby red is not to be as easily driven away as is the lighter hue of older persons. No deductions can be drawn, moreover, from the dark hue of the face, for this may have been the result of prolonged pressure upon the head during the birth. In that group of appearances which result from the attempt to carry on the process of respiration under water the differences to be expected would be less; yet we should hardly look for the signs to exist in the same degree as in the case of adults. The more feeble the life the shorter and less vigorous the struggle of its possessor to preserve it. The case reported, if exceptional in this respect, proves that the child was unusually strong. I place little reliance upon the minor indications of drowning as shown by the autopsy, such as the presence of water in the stomach, the fluidity of the blood, the accumulation of blood on the venous side of the circulatory system, the congestion of the lungs, etc., for the presence of liquid and froth in the respiratory passages seems sufficient in itself to establish beyond question the cause of death. This being settled, the only question remaining to be considered was whether the drowning was accidental or not. There being good reason to suppose that the mother willfully destroyed her child, she was arrested on the charge of infanticide, bound over from the police court, indicted by the grand jury, and released on bail without a hearing from the superior court. At the preliminary hearing the attorney for the defense vaguely shadowed forth two theories to account for the death of the child: one, that the mother drowned it while laboring under puerperal mania; the other, that it was accidentally drowned in the liquor amnii during, or soon after, the birth.

The first theory is not one that would have much weight with medical men; for it is incredible that a woman should develop mania after her confinement just sufficient in degree and duration to allow her to destroy her child, and that she should become perfectly sane and well a few hours afterwards, so as to show no trace whatever of the malady. Her own story, told with the object of relieving herself from suspicion, would of itself effectually dispose of this theory. The second theory is much more plausible than the first; yet there are certain circumstances which make it clear to my mind that the child was willfully murdered. In the first place the quantity and quality of the liquid in the respiratory passages of the child prove that it was drowned, not in a small pool of the discharges, but in an abundance of water. The city marshal stated that the contents of the vault were frozen; that the surface of the child was moist and steaming, but not wet. That he took it out by the feet, head depending,—an act which would allow much of the liquid in the child to escape. Notwithstanding this, and the wetting of

the paper in the bottom of the box during the journey to the City Hall, enough liquid remained to run in a stream from nose and mouth when the child was taken out and placed upon a table. Besides, the liquid was clear like water, presenting no traces of fecal matter, blood, or slime. If the girl's statement was true, that the child was born while she was sitting over a pail, we are to believe either that there was water in the pail, and that the child fell at once into it and was drowned before it had time to cry or manifest to her other signs of life, or that the breaking of the bag of waters furnished liquid enough, together with urine, etc., to drown the child. In the former case respiration must have been performed so as to completely expand the lungs in every part while the child was dropping through a space of a few inches at most. If the pail were half full of water the head would enter it at once. As the perinæum was ruptured, the extrusion of the child must have been sudden. It is not to be admitted that respiration could have been performed while the child's head was within the vagina, for the head was large, and the mother a primipara. Even if the head were extruded, and the body held back by the shoulders, attempts at respiration could only have imperfectly expanded the lungs at best. But the rupture of the perinæum makes it almost certain that this delay did not occur. We are then justified, I think, in concluding that the girl's statement was false. She could have invented such a story only with the purpose of covering up some offense of her own. Hence there is little doubt that the birth took place upon the cellar floor, and that the mother, after severing the cord with some rude instrument, deliberately drowned her child in a pail of water.

NOTES OF PROGRESS IN PHYSIOLOGICAL CHEMISTRY.

BY JOSEPH W. WARREN, M. D.

NOT the least pleasant record to be made here is the appearance of a new edition of the well-known hand-book of Hoppe-Seyler.¹ An old friend of all workers in this department, the new edition shows everywhere a praiseworthy endeavor to keep abreast of the times. Many less satisfactory methods have been omitted, and condensation practiced where permissible, and still the fifth edition contains fifty pages more than its predecessor. Without going too much into detail, we note some of the changes which are apparent even on a hurried examination of the book. There is a new and sufficiently brief chapter on testing the reaction of liquids, and in another place rosolic acid, alkanna, and tropæolin receive due attention. The new remarks on the use of the spectroscope for quantitative analysis (page 21) are sensible and to the point. There are many new chapters about the multitudinous compounds which have been found in recent years, among others acetone, hydrochinon, the various compound sulphuric acids, skatol, etc. The chapter on urea contains much new matter, and that on glycogen is enlarged, but here, as elsewhere, too little attention is paid to the difficulty of completely extracting the tissues. There is a new chapter on maltose, but the chemistry of this substance is hardly full enough. In the chapter on grape sugar Worm-Müller's

laborious investigations are fully regarded, and the chapters on the proteid bodies are full of newer and interesting details. In this, as in the previous edition, no account is given of gasometric analysis proper, a misfortune to the student surely. There is also no mention of the new cadaveric alkaloids or ptomaines, but, perhaps, these belong too much to the department of toxicology, yet hardly more so than some subjects treated in detail in the hand-book which are really the product of a kind of poisoning. Leaving captiousness aside we may say, then, that the new edition has all the clearness, convenience, and compactness which have characterized former editions, and remains an indispensable aid to all students.

Another recent book ought also to find a brief notice here, the closing half volume of Hermann's Hand-Book of Physiology.²

This division of the work was originally assigned to Huppert, but was finally taken in hand by Drechsel, who has prepared it somewhat more hurriedly than he wished, as he has explained in his little preface. The result is, however, an interesting account of the chemistry of the principal secretions and tissues, excepting the digestive and some other secretions, as the bile, which, together with the chemistry of muscle and blood, had been already considered in other portions of the book. The chemistry of the urine is given with great brevity, but very pleasantly, and special attention is paid to the new bodies, compound acids, that have attracted so much attention of late. The chapter on milk is brief, but sufficient; that on fats and similar substances exceedingly good and suggestive. The section on connective and epithelial tissues is shorter than some authors have led us to expect, but it contains the principal facts in a convenient form. It would, indeed, be difficult to write a better succinct account of these portions of physiological chemistry than Drechsel has given us in some 175 pages, of which ninety-four are devoted to urine. The directions for quantitative analysis are everywhere reduced to a minimum, and in one important case, that of dextrose, omitted altogether. The principal criticism which might be made against the book, that it tends to be too chemical and too little physiological, is disarmed by the author in his preface.

Some twenty years ago Schiff reported that the pancreatic juice or extract no longer digests albumen if the spleen have been previously extirpated. More recently it was found by Heidenhain that the zymogen, or forerunner, of trypsin is formed in the pancreas quite independently of the presence of the spleen. A couple of years later Herzen looked into this discrepancy, and decided that although the zymogen is thus produced independently its transformation into the proteolytic ferment (trypsin) depends upon a ferment furnished by the spleen. His conclusions were based upon too few observations to be altogether satisfactory even to himself, and he has therefore recently repeated them, and published the results of some twenty experiments³ which he has made. He seems to have demonstrated pretty conclusively that a proper spleen, one which is enlarged and blood containing during digestion, produces a ferment extractable with glycerine or a five per cent. solution of boric acid, which, when

¹ Handbuch der Physiologie. Fünfter Band, zweiter Theil, zweite (Schluss-) Lieferung. Chemie der Absonderungen u. Gewebe, von E. Drechsel. Leipzig. Vogel. 1883.

² Herzen: Ueber d. Einfluss d. Milz auf d. Bildung des Trypsins, Arch. f. d. ges. Physiol., xxx., 295.

³ Handbuch der physiologisch- u. pathologisch-chemischen Analyse für Aerzte. Studiende, von F. Hoppe-Seyler. 5te Auflage. Berlin. 1883. Hirschwald.

added to the extract of the pancreas, causes a very marked increase of proteolytic action. He found the boric acid useful in delaying the spontaneous transformation of the zymogen into trypsin. At first he supposed that this change was altogether prevented, but such did not prove to be the case. It seems that a shrunken and anæmic spleen is not absolutely inert, but very much less active than a healthy one. He has made no experiments on splenotomized animals which might furnish an interesting means of verification. It should be added that the effort to find the ferment in the liver and kidney led to negative results. The importance of establishing such a splenic function and its bearing on the pathology of nutrition need no comment.

In another briefer communication¹ the same author reports an interesting result of asphyxia with carbonic oxide on the formation of trypsin. Bearing in mind that the change of the zymogen was apparently affected by taking up oxygen, he thought by using some convenient reducing agent to hinder this transformation. It seems that the pancreatic extract of dogs thus killed has much less than the normal digestive power; there is less trypsin present than the condition of the animal would lead one to expect. In other words, even some of the trypsin already formed has probably been *reduced* to zymogen. Indeed, it is sometimes possible to render such an extract more active by driving out the CO with oxygen. From these and other experiments Herzen comes to the curious result that poisoning with carbonic oxide affects *only* the trypsin, while poisoning with carbonic dioxide alters *none* of the ferments.

The physiology of the saliva has lately received considerable attention from several investigators. The effect of acidification on its specific activity has been newly tested by Nylén,² who took up this question at the suggestion of Hammersten. Mixed saliva was neutralized and then mixed with hydrochloric acid in suitable dilutions (0.025–0.1 per cent.). The amylolytic power of this mixture after standing a suitable length of time, and after being again neutralized, was carefully tested. A varied control was exercised by means of an unneutralized portion, and by acid alone with starch. Nylén found that an acidity of 0.075–0.1 per cent. suffices to permanently destroy the diastatic value of the saliva. Experiments with acid and pepsin led to similar results, only the destruction seemed somewhat less easy; it required a slightly stronger acid. It seems, then, that the ferment in question (ptyalin) becomes inert in a mixture of lower acidity than we usually find in the stomach during digestion. The saccharification of the starchy foods may then continue for a certain time while gastric digestion is beginning, but only until the dangerous point of acidification is reached. Once thus destroyed, for it seems that we have to do with no mere inhibition, the neutralization in the small intestines would not recuperate the ferment. In other words, in the case of a mixed diet we are not justified in supposing that salivary digestion continues long in the stomach or is resumed in the intestines beyond. A liquid food which underwent no coagulation in the stomach might not remain long enough in that organ to become

acid, and could thus keep up whatever digestion the saliva brought with it might be capable of effecting. But such foods are not likely to cause much flow of saliva except, perhaps, when taken in small quantities and slowly, with considerable alterations of the pressure in the mouth, as in drinking from a bottle. This view had, indeed, been already pretty generally adopted, but the confirmatory evidence such as Nylén has furnished had been lacking.

A similar result is arrived at by Langley and Eves,³ but these authors differ from the Swedish investigator as to the amount of acid necessary for the destruction of the amylolytic ferments, differences, however, which do not materially affect the main question of the continuance of this digestion in the stomach. An explanation of the discrepancy seems to lie in the influence of the neutralizing acid on the proteids in the saliva, and Nylén may have neglected to allow for this, or are there national differences in saliva?

Fenwick has studied the same secretion from a different point of view.⁴ He was specially interested in examining the quantitative behavior of the mysterious sulphocyanide of potash, particularly with reference to disease. The comparison was made on colorimetric principles, using the chloride of iron, a convenient and handy method, to be sure, but open to some serious objections. Fenwick corroborates anew the view already general that the presence of this curious substance is in no way associated with defects of the teeth, and furnishes no evidence of the use of tobacco. Although the pathology of the subject does not strictly concern us here, we may add that the amount of SCyK seems to be diminished in icterus, or more exactly in those cases where the entrance of bile into the intestines is interfered with. It is also less in many diseases where the injury to nutrition is or becomes prominent, for example, constriction of the œsophagus, carcinoma of the stomach, dyspepsia, dysentery. Lead-poisoning is also said to have a similar effect. An increase is noted in cases with a tendency to great development of adipose tissue, in acute rheumatism, and in the earlier stages of all diseases accompanied by fever and inflammation, that is, before the injury to nutrition becomes prominent.

These results are said to be based on the examination of one thousand persons. Should they be confirmed an interesting diagnostic field will be opened to all but the color-blind. Ere long a compact and convenient sialoscope must doubtless be added to the physician's equipment, and a new tribe of sialogists will, perhaps, enlarge the number of specialists, and, possibly, enrich medical literature with an "Archives" and even a "Centralblatt."

— A novel mode of blood-letting is given in a late number of the *British Medical Journal* by Dr. Charles Coppinger, who relieved a serious cerebral congestion by introducing the aspirator needle into the external jugular vein, and abstracting at first four ounces of blood, and half an hour later six ounces more. The patient was a fat and plethoric lady, fifty years of age.

— Carey, the informer, who was murdered by Irish agitators, had a brain weighing sixty-three ounces.

Hospital Practice and Clinical Memoranda.

KAIRIN AS AN ANTIPYRETIC IN TYPHOID FEVER, WITH CASES.¹

BY GEORGE B. SHATTUCK, M. D.,
Visiting Physician, Boston City Hospital

THE importance attributed by the German clinicians of the present day, as represented by Liebermeister, Brand, and others, to the part played by the pyrexia in acute febrile diseases is well known. In their view the pyrexia is the exhausting factor of the disease, and if this can be controlled, eliminated, or suppressed, the disease process itself will be conducted by a more comfortable path to a speedier and safer conclusion.

This view has been hitherto regarded as false by the more prominent French clinicians, and in England and our own country, if not considered as exaggerated, has, at least, been but very partially acted upon. Whatever theory may be entertained upon this point, however, there is no question of the welcome which would be extended by the profession in all countries to an antipyretic medicine which should prove itself at once efficient, prompt, safe, and tolerably uniform in action; not too rapid in elimination; moderate in price; and reasonably easy of administration. The list of antipyretics in actual use is probably exhausted when we have named quinine, digitalis, salicylic acid with its compounds, and the application of cold in some form. None of these serve all the indications mentioned, and most of them serve several of these indications but very imperfectly. Under these circumstances the announcement about a year ago of the discovery in Germany of a new antipyretic compound of unusual force excited some little interest.

The first notice of this new compound, kairin, in this country, with which I am acquainted, appeared in the Boston Medical and Surgical Journal of December 14, 1882, in a short editorial article written by Dr. F. H. Williams. Since then it has attracted attention in other quarters, and in his report on Progress in Therapeutics in the JOURNAL of September 20, 1883, Dr. Williams gives the latest published results of its use in Germany. I know of no reported cases of its use in this country.

I ask your attention, therefore, to six cases of typhoid fever at the City Hospital this summer in which kairin was used, five of them occurring in my own service, and one in that of Dr. A. L. Mason. I am quite aware that the number of cases is too small to prove much, that they exhibit the action of the antipyretic in only one kind of acute febrile disease, and that the administration was not in all respects as well adapted to demonstrate the action of kairin as it might have been in some of the cases. But it is by comparing the results of a number of unprejudiced observers that we arrive at the truth in these matters, and these cases should at least be worth comparing with others as reported, by whose reflected light they may be illuminated.

I should have been glad to test the antiperiodic properties of kairin as well as its antipyretic, but it is only quite recently that its market price here permitted its use. As lately as last July it was sold here for

\$2.50 a drachm, but since then could be purchased in quantity for fifty cents a drachm, or a little less than a cent a grain. It is now sold for \$3.75 a drachm, and I believe that the process employed for its preparation may with an increasing demand be so improved it to be sold at a much cheaper rate, and make it considerably cheaper than quinine.

Since being provided with kairin I have not had a suitable case of intermittent upon which to test it; neither have I used it in pneumonia, for, in addition to being disinclined to use antipyretics in pneumonia except in a very limited way, such cases as occurred during a summer's service at the City Hospital pursued a perfectly regular and satisfactory course and required no active interference. I have therefore only an experience with kairin in typhoid fever to offer you, and a very limited one at that.

I have with me, and will pass around, the charts of the cases as showing more readily and truthfully than in any other way the action of the kairin. To judge from these cases alone one would be inclined to conclude, I think, that kairin as an antipyretic is very efficient, prompt, and reasonably safe in action; but that its effect passes away very quickly, its elimination being rapid; that it is not very uniform in its action, and that, as the proper dose has to be sought to a rather unusual degree in each individual case, and as the dose as a rule has to be repeated and the temperature taken at very short intervals, its exhibition is attended with a good deal of inconvenience, and should be intrusted to intelligent persons. In other words, kairin leads one to believe that a better antipyretic is possible, and that such will probably be ultimately arrived at, it may be by further experiments in the same direction which led to its discovery.

Only two of the charts show the respiration as well as the pulse and temperature; the records on all were made hourly during the exhibition of the kairin, and the dose where not specified was half a gramme, or seven grains and a half, the half dose indicated being half that amount.

Chart No. I. represents a patient in the service of Dr. Mason, who was not naturally a strong man, and who was considerably reduced. Kairin was administered very cautiously, and yet marked depression and cyanosis resulted, necessitating quite free stimulation. Three successive full doses reduced the temperature three and a half degrees in three and a half hours, but two more hourly doses given after the lapse of an hour did not prevent its rising six degrees in two hours. The next day half doses were given, and on a subsequent day three successive full doses, again carrying

¹ Read before the Clinical Section of the Suffolk District Medical Society, October 10, 1883.

the temperature down four degrees in three hours, only to have it rise again five degrees in two hours.

Chart No. II.¹ exhibits kairin in its most pleasing aspect. The patient was a particularly robust German, — who probably had an intuition that the honor

of the Vaterland was involved, — with a temperature of 104° F., and a pulse of 75. After eight hourly full doses of kairin given between seven P. M. and two A. M., the temperature continued to fall until normal was reached at noon, the pulse falling fifteen beats. The temperature then rose five degrees in twelve hours, and then fell steadily and rapidly, not rising again above 100.2° F.

The case represented by Chart No. III. was that of a vigorous man, reported as never having been sick in

his life before. He had a very good pulse, only 85. Owing to a mistake on the part of an attendant, kairin was given ten times in succession, hourly doses of seven and a half grains, and it was not begun until two hours after it should have been. The temperature, already falling, was carried down from 101.5° F. to 95° F., and the pulse from 75 to 55, between nine P. M. and six o'clock A. M. At ten A. M. the temperature had risen to 103.5° F., and the pulse to 108. The fall and rise were each accompanied by a chill. There was marked cyanosis and cardiac depression, and stimulants and heaters had to be freely resorted to. The subsequent history of the case was normal, and the patient is convalescent.

Chart No. IV. is that of a robust man, who had been treated in the hospital last May for cerebrospinal meningitis. The afternoon of the day upon which kairin was begun, and one hour before, he had a temperature of 105° F., and a pulse of 80. Six successive hourly doses made little immediate impression.

¹ By mistake in this Chart two doses of kairin are omitted.

Six hours later the pulse had fallen three and a half degrees. Two days later eight successive hourly doses

Chart No. II. CHART NO. II. Nov 1/83

were given, beginning at the same hour, five P. M., and the temperature was carried down four degrees, but rose in two hours four degrees and eight tenths, and fell to the same extent spontaneously in three hours, only to rise again. The pulse in this case varied but little.

Charts V. and VI. show the marked effects of only three successive half doses of kairin upon women who

Chart No. V. CHART NO. V. Nov 1/83

were somewhat reduced in strength. In these cases the pulse was reduced thirty and twenty beats respectively, and the respiration twenty points; the temperature being carried down in No. V. six and a half degrees in three hours, returning to the original point in

Chart No. VI. CHART NO. VI. Nov 1/83

seven hours, and in No. VI. it fell six degrees in the same time to rise six and a half degrees in two hours.

Dr. Williams's articles, already mentioned, give all the details at present accessible in regard to kairin, with references to original sources of information. I will merely repeat, therefore, that the chlorhydrate is

a crystalline, nearly white, powder, readily soluble in water, having a mixed salt, bitter, and aromatic taste. It was, in common with other antipyretic compounds, prepared by Drs. Fischer and Koenig in Munich in the course of two years of experiments upon various imitations of the quinoline-hydrogen compound in quinine. Professor Filehne, their associate, made the first clinical experiments with it.

The method of administering it in the case of a vigorous adult is to give half a gramme every hour from four to six times consecutively until the temperature falls to 100° F., and to keep the temperature down it must be continued in smaller doses. Such an administration is accompanied by free perspiration. When the medicine is omitted for two or three hours the temperature rises to the original point or higher, and this rise is accompanied by a chill which may be regarded as an indication for renewing the kairin. An overdose causes a feeble pulse, and cyanosis of the lips and extremities, — a condition requiring stimulants. Experiments by Dr. Girat upon animals fix the toxic dose at one to two grains to the pound weight of the animal. Drs. Riegel and Seifert observed these depressing and toxic effects in pneumonia with only moderate doses. That individual idiosyncrasy and physical force must be duly regarded is sufficiently illustrated among the few cases I report. The effects of kairin are manifested rapidly, and it is found in the urine, which becomes of a dark-green color about half an hour after the first dose is taken. This coloring of the urine is sometimes accompanied by a slight trace of albumen, not differing in amount from that often found in typhoid fever. The present cases indicate that its effects pass off even more rapidly than they are produced. Apart from the cardiac depression in two cases no unpleasant results were experienced from the medicine, and this agrees with previously reported observations. In this respect, certainly, kairin seems to have a decided advantage over quinine or salicylic acid; its action, moreover, is said not to be cumulative, nor is a tolerance established in the system. As before said, the present cases lead one to suspect that it is not very uniform in its action. They illustrate its action as an antipyretic, but are not offered to show its effect upon typhoid fever.

TWO CASES OF TYPHOID FEVER IN WHICH KAIRIN WAS GIVEN.¹

BY DR. F. W. DRAPER,
Visiting Physician, Boston City Hospital.

HENRY T., aged forty, reported that he had been sick twenty days when he entered the City Hospital, March 10th. He had not been obliged to go to bed. He had had chills, anorexia, nausea, diarrhoea, and fever; scanty urine and headache with tinnitus aurium.

When admitted as a patient to the hospital he had headache, a compressible and dicrotic pulse, diarrhoea, tympanites, and iliac tenderness. Evening temperature 103.5° F.

During the next six days there was no noteworthy change.

On the twenty-sixth day of the disease, as the patient reckoned it, his morning temperature being

102.4° F., and his pulse 110, he had hourly doses of kairin from noon till nine P. M., half a gramme at a dose. The first effect noticed was a reduction of the temperature from 102° F. to 101° F. Three hours after suspending the drug, the thermometer registered 104.4° F. Eight hours later than this the temperature was 101.4° F. After three doses the patient

~~CHIEF CLERK~~ ~~in March 1883~~

had considerable sweating, and shortly after that a chill; a second chill accompanied the rise following the suspension of the medicine. The pulse was but little affected.

The condition of the patient subsequently presented no remarkable features. Marked weakness, as shown by dicrotic and compressible pulse, was noticed; but convalescence progressed, and the patient was discharged well, April 10th, a month after his admission, and forty days after the onset of the attack.

Geo. M. M., aged thirty-five, entered City Hospital March 9, 1883, having been sick eight days. He had had chills, anorexia, headache, and the usual train of symptoms attending an attack of typhoid fever at its

~~CHIEF CLERK~~ ~~in March 1883~~

beginning. He entered with a temperature of 103° F., and a pulse of 110.

Next day (March 10th, the ninth day of the disease) he complained of abdominal pain, with moderate tenderness and tympanites. His spleen was enlarged. There was diarrhoea, with the characteristic typhoid dejections.

On the tenth day he was a little better; he had slight headache, and his diarrhoea was under control.

On the eleventh day diarrhoea returned, the dejections containing undigested milk.

On the twelfth day rose spots were observed for the first time.

On the sixteenth day his temperature was 102° F. in the morning. His diarrhoea continued. His mind was clear. His strength and general condition were

¹ Read before the Clinical Section of the Suffolk District Medical Society, October 10, 1883.

maintained fairly. His continued high temperature (as the chart shows, it had fluctuated between 104.2° F. on the day of his entrance and 102° F.) gave some ground for uneasiness, and suggested that he would be a good subject for an experimental trial of the new antipyretic, kairin. Through the kindness of Dr. F. H. Williams, a supply of the new agent was obtained, and the patient received half a gramme every hour for six hours. The effect on the temperature is shown in the chart. In four hours there was a reduction of 4.6° F., attended with copious sweating. In the fifth hour a very severe chill occurred, followed in two hours by a rapid rise of the temperature to 104° F. At the discontinuance of the treatment the temperature was 101° F. Two hours later it was 99.4° F. Eight hours after the last dose the register was 102.6° F. The pulse fluctuated with the temperature, but the disturbance was less in the pulse than in the temperature. The appearance of the patient during the administration of the kairin was peculiarly distressing, his face being pinched and his expression anxious, although he did not complain of any unpleasant sensations.

Next day there was some reaction, and the temperature touched its highest point, but during the two following days there was a steady decline, and the condition of the patient was more hopeful.

Eight days after the experiment, however, unfavorable symptoms developed, diarrhoea increased, the tongue became dry, there was delirium and a marked prostration.

From this time forward the decline was progressive, and the patient died on the thirtieth day of the disease, and fifteen days after the experiment with kairin.

The autopsy discovered the usual typical ulcerations of the small intestine peculiar to enteric fever.

ing not only deafness, but more serious symptoms, by extension of the process. There is certainly no reason for leaving the ear entirely out of consideration in the diagnosis and scientific study of nervous diseases. The eye has been so carefully studied for some time among neurologists that the diagnosis of locomotor ataxia or cerebral tumor without ophthalmoscopic examination is the exception, and the symptom "blindness" without further explanation would be considered an absurdity. Although we cannot assume that an equal amount of advantage is to be expected from the study of the ear, there is certainly much to be gained, and it should not be altogether neglected.

As an example of the practical value of adding otological to neurological study may be mentioned the recent investigations into hysterical deafness, which have shown that it has pathognomonic characteristics, the hearing through the bone disappearing first, then that for high tones. A knowledge of these characteristics is not only of value in diagnosing simple hysteria, but also medico-legally in examining the hysterical symptoms following railway and other injury, as pointed out especially by Dr. J. J. Putnam¹ and the reader. A case has, however, been recently reported by Landan and Remak, in which left-sided hemianæsthesia of hysterical origin was accompanied by deafness on the opposite side. No examination of the ear was made and the hearing was only tested by the watch, and that only in the air, so that the right-sided deafness may as well be attributed to middle-ear disease, for example, as to the hysteria, though no conclusions at all can be drawn from such incomplete evidence.

A systematic review of published cases in German, French, English, and American journals shows that while the eye is rarely, the ear is generally, left out of consideration in diagnosing cerebral disease. The cases in which the ear is neglected may be classed as follows: (1) Those in which no note whatever is taken of the condition of the hearing, although the presence or absence of deafness would be of diagnostic value; (2) cases in which deafness is mentioned as a symptom in nervous disease without sufficient examination to exclude disease of the ear itself.

(1.) The first is by far the most numerous class, and includes, perhaps, the large majority of cases of cerebral lesion, such as tumor, hæmorrhage, and abscess, to say nothing of hysteria and allied disturbances. Why the auditory nerve should be left out in the otherwise systematic analysis of such cases is not clear. The presence or absence of deafness would be of importance, for example, in question of lesion of the pons or cerebellum. Seymour² has recently reported a case of cerebellar tumor pressing on the pons, in which deafness by air and bone added much to the certainty of the diagnosis afterward corroborated by autopsy. Although this case comes under the second class mentioned in that no examination of the ears was made, the probabilities were in favor of the tumor as the etiological factor, and the case is quoted because Nothnagel in his text-book on diagnosis of cerebral diseases states that no case of deafness is on record resulting from cerebellar disease. The same writer states that the auditory nerve is not often affected by tumors and hæmorrhages of the pons, basing this opinion on the

Reports of Societies.

PROCEEDINGS OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.

ALBERT N. BLODGETT, M. D., SECRETARY.

OCTOBER 10, 1883. Meeting called to order at eight o'clock, Dr. G. B. SHATTUCK in the chair.

There being no pathological specimens for exhibition, the first business of the meeting was the reading of a paper on

THE NEGLECT OF EAR SYMPTOMS IN THE DIAGNOSIS OF DISEASES OF THE NERVOUS SYSTEM,

by DR. G. L. WALTON, of which an abstract follows:—

The study of the ear symptoms in nervous diseases has not kept pace with the general advance in neurology during the past twenty years, although otological research itself occupies at present a front rank in scientific progress.

It is not to be expected that the general practitioner should gain a thorough knowledge of the ear, but it is unfortunate that he should neglect it entirely, as in the exanthemata, where a little knowledge of otology would sometimes prevent, for example, a hyperæmia from becoming a purulent inflammation, caus-

¹ Boston Medical and Surgical Journal, September 6 and October 11, 1883.

² Boston Medical and Surgical Journal, August 30, 1883.

fact that deafness is rarely mentioned in reports of such cases. He says himself that the fact is remarkable, considering the situation of the auditory nerve. The most probable explanation of the seeming rarity of deafness in cases of disease of the cerebellum and pons is that it is seldom sought for, deafness being a symptom which often eludes the observation of both patient and physician, because fair hearing in one ear usually suffices until special attention is called to the subject.

(2.) Deafness is frequently mentioned as a symptom of nervous disease by observers otherwise most accurate, with no examination or only superficial examination of the ear, so that the reader is often left in doubt as to whether the deafness is really due to the nervous lesion (tumor, locomotor ataxia, etc.), or to a plug of cerumen or catarrh of the middle ear. In exceptionally careful reports sometimes occurs the statement, "membranes normal," but apparently normal membranes may coexist with extensive disease of the middle ear. In such cases the hearing through the bone is of great value, for this is generally apparently increased in disease of the middle ear and diminished or lost in case of nervous lesion.

Even when disease of the outer and middle ear is eliminated we are not justified in jumping at once to the brain, as there still remain the inner ear and the course of the nerve fibres to the brain. How unscientific, therefore, is the record of "deafness" among the symptoms of cerebral tumor or locomotor ataxia without further particulars.

Amongst other inaccuracies may be noticed the fact that the patient's own statement is often relied on in eliminating the question of deafness as a symptom. The patient's statement that he hears well is, however, of absolutely no value, a total deafness of one ear going sometimes unnoticed for an indefinite length of time until suddenly revealed by accident, as by rolling over upon the well ear in bed.

Even the regular tests by the voice, tuning-fork, and rods are subject to such inaccuracies as to require careful study and repetition in the given case. Deaf children are often brought to the aural clinics who not only deceive their parents, but who would deceive the medical practitioner unless he exercised great care, because they turn so quickly when a noise is made near them that it seems as if they must have heard it. The same children will, perhaps, take no notice of the shrillest sound if made stealthily behind the head by an experimenter who remembers that the field of vision extends laterally over not far from 180 degrees when the head remains quiet, and much farther when it is continually in motion.

As an example of lack of care in eliminating disease of the ear itself as causing deafness, cases of locomotor ataxia, notwithstanding the efforts of Professor Lucae, have been repeatedly mentioned with deafness as a symptom, and with no examination, or the most superficial examination of the ears. If the ears were carefully examined the cases of deafness as a symptom of locomotor ataxia would probably be reduced to a minimum.

The reader has failed, indeed, to find a single case during a careful search through forty cases, most of the patients being more or less deaf. "Menière's disease" is often diagnosticated with no examination of the ears, while the so-called Menière's complex of symptoms is so common in disease of the middle and outer ear as to

reduce greatly the number of cases in which otologists attribute them to nervous lesion.

It is not the object of this paper to contend that the skill of an otologist should be added to the requirements for neurological training. It is rather to offer the suggestion that the ear deserves an interest at least approximating that accorded to the eye in the diagnosis of nervous diseases. It would certainly be desirable that every practitioner, whether neurologist or not, should practice the examination of the ear and hearing to such an extent as to avail himself at least of the aid gained from the appearance of the membranes, the patency of the Eustachian tubes, and the hearing by air and bone by the various tests, as well as the hearing for different tones, before making a diagnosis of lesion of the nervous auditory apparatus. And further, it is to be hoped that the time is not far distant when reports of cerebral disease ignoring the condition of the hearing and the examination of the ears will be considered as incomplete as they are at present without record of the condition of the eyes.

DR. C. J. BLAKE said that, in addition to the general interest of Dr. Walton's paper, his remarks point a moral, namely, the dependence of specialists in medicine upon each other; for, while in investigations in physics special students pursuing parallel lines of research help each other to draw cross inferences, in medicine the lines of research in different departments are constantly coinciding, the cross inferences are already drawn by nature. The research of each specialty, therefore, complements and enlarges that of the others, and herein lies one of the safeguards against the narrowing tendency of specialism.

Dr. Walton's paper also contains an important hint to otologists in regard to the investigation of those disturbances of function which may be due either to an affection of the middle or the internal ear, or to both combined; a review of records of aural clinics during the past fifteen years, for instance, shows that the percentage of cases recorded as "disease of the inner ear," or as "nervous deafness," has steadily decreased, this decrease is due to the advancement in the knowledge of diseases of the external and middle ears, the sound-transmitting portions of the organ of hearing, making possible the proper classification of many diseases which were previously relegated to the limbo of "nervous deafness" for want of better knowledge. While the great progress which otology has made during the past fifteen years has been in the study of the middle ear principally, enough has been done and is doing in the investigations of the relations of the ear to the brain to show that the advance of the future is undoubtedly to be in the direction of neurological research.

DR. B. O. KINNEAR inquired the seat of the cerebral centre of the auditory nerve.

DR. WALTON said it was supposed to be situated in the first temporo-sphenoidal convolution. Functional disturbances of this portion of the brain may be accompanied by impairment of the sense of hearing. In a recent report in one of the journals was the diagram of an abscess occupying the exact seat of the auditory centre, but no allusion was made to the condition of the auditory function. Concussion of the cerebral substance has been followed by temporary disturbance of hearing, whether by vaso-motor or molecular disturbance is uncertain.

DR. GEORGE B. SHATTUCK read the next paper, upon the subject of

KAIRIN AS AN ANTIPIRETIC IN TYPHOID FEVER, WITH CASES.¹

DR. F. W. DRAPER read an account of two cases of typhoid fever also treated by kairin,² and expressed the opinion that thus far the employment of this new substance has not been followed by better results than have attended the use of the more common agencies for the treatment of fever, which latter if less energetic in lowering the temperature are followed by no alarming symptoms, while in certainly one case in which kairin was administered the immediate effects of the drug were dangerous to the life of the patient.

In reply to Dr. J. P. Reynolds, who asked the further history of Cases IV., V., VI. of Dr. Shattuck's report, the latter explained that the cases were not given in full as his object was not to report cases of typhoid fever, or even of the effects of kairin upon the *disease*, for which purpose its exhibition had not been sufficiently long continued, but merely to report without prejudice practical tests of the action of the new remedy upon the *pyrexia* of typhoid fever and upon the patient as an individual. Dr. Shattuck did not think the course of the disease had been really modified in any of these cases, with the exception possibly of No. II., and in that the modification attributable to kairin may have been more apparent than real. This patient experienced a relapse after two weeks of continuous convalescence. In Cases I. and III. the kairin produced great depression of the patient's strength. The lips became pinched, the extremities were livid, and the respiration embarrassed. One of the female patients was also very much depressed by the drug.

DR. REYNOLDS remarked that it is strange that any medicine should cause a sudden and great decline in the temperature, to be followed immediately by a rise to even a higher degree than the original temperature.

The greatest benefit which is at present apparent from the action of this drug seems to be that which is obtained from the temporary reduction of the temperature, for it is now an accepted fact in all febrile diseases that the condition of the patient is always more hopeful when there are remissions in the temperature than when the high temperature is continuous.

DR. SHATTUCK said that in some of the cases in which the temperature was high, even 105° F., the pulse presented no corresponding rate of frequency. Antipyretics were not called for by the actual severity of the disease, but the drug was administered in order to give these patients all the benefits of recent therapeutics.

DR. REYNOLDS observed that ordinary cases of typhoid seldom call for the employment of antipyretics or for any marked or special treatment. Such patients do very well under careful nursing with very little medication.

In answer to Dr. E. G. Cutler, the reader said that the peculiar dark-green color is the only gross evidence of the elimination of kairin by the kidneys, and there is nothing characteristic about the perspiration. A quantitative analysis of the urine was not made, and the trace of albumen found is common in typhoid or other fevers.

The German description of the action of the drug was pretty closely reproduced in most of the cases here reported.

² See page 417 of this number of the JOURNAL.

NEW YORK ACADEMY OF MEDICINE.

THE PROPOSED AMENDMENTS TO THE CONSTITUTION AND BY-LAWS LOST.

ONE of the largest meetings ever assembled in the halls of the Academy was held on Thursday evening, October 18th, when final action was taken on the amendments to the Constitution and By-laws recently proposed by the President, Dr. Fordyce Barker. In accordance with the arrangement made at the last meeting, the Academy first went into committee of the whole for further discussion of the amendments, with DR. ELLSWORTH ELIOT in the chair.

DR. AUSTIN FLINT, JR., was the first speaker. He had very little to say, he remarked, except a few words of an explanatory nature similar to those which he had uttered at the meeting two weeks before. He still thought there was not the slightest necessity for discussing the proposed amendments either in the Academy itself or in committee of the whole, and it seemed to him and to others that there was no reason why a scientific paper should not have been read before the Academy at the last meeting instead of taking up valuable time with a discussion upon a matter upon which no action could then be taken. It would have been sufficient to announce that certain changes were proposed in the Constitution and By-laws, on which a vote would be taken at the following meeting, and then the scientific business might have gone on as usual. He humbly submitted that both the mover and seconder of the adoption of the amendments were clearly out of order in the addresses which they made at that time, for the reason that there was nothing before the meeting, since the question of the amendments could not legally come before the Academy until the present occasion. He was simply the spokesman, he continued, of a certain number of gentlemen who believed that the welfare of the Academy would be best promoted by adhering to its Code of Medical Ethics, which was that of the American Medical Association. The issue was perfectly clear to every mind, and he did not believe that any amount of eloquence would convert those misguided members who wished to do away with that. The amendments had one great object in view, and that was the elimination of everything which related to medical ethics, and every Fellow who was an upholder of the National Code would vote against them, while every one who was in favor of the new Code would vote for them. Their adoption would leave the Academy with no code at all, and that he considered even worse than to adopt the new Code. Dr. Flint then called attention to two of the proposed amendments in regard to the Council, one of which took away from it the power of appointing delegates to other societies (which was simply making a virtue of necessity, since if the amendments were adopted such delegates would not be received), and the other of which reduced the quorum of the Council from nine to five members, which, considering the number and importance of the functions belonging to that body, he believed to be exceedingly objectionable. He then went on to say that he was informed that at no time in the history of the Academy had any amendments to the Constitution and By-laws ever been adopted which had not first been indorsed by the Council, and also that at no time in the history of the Academy had a recommendation from the Council failed to be acted on. At the last meeting a dignified

protest against the passage of the proposed amendments had been communicated to the Academy by the Council, and it had not even received the scant courtesy of a motion that it be placed on file. In conclusion he said that he and his friends desired to preserve the Constitution and By-laws as they are, and that as they had registered more than one fourth, not of those present, but of the entire membership of the Academy, it was ridiculous for any one to suppose that the amendments could receive a three-fourths vote. He then moved that the committee of the whole should rise, and this was carried.

The chairman of the committee, DR. ELIOT, made his report, and DR. CARPENTER, the secretary, read the resolutions recommending the adoption of the amendments which had been passed by the committee when in session at the last meeting.

DR. FLINT, JR., moved that the report of the committee of the whole be laid on the table, on which motion DR. D. B. ST. JOHN ROOSA called for the ayes and nays. The PRESIDENT decided that the register on which the members had inscribed their signatures on entering, instead of the roll of the Academy, should be used in calling the names. This decision was appealed from, but was sustained by a vote of eighty-eight to eighty-four. The ayes and nays were then taken on the motion to lay the report of the committee of the whole on the table, and it was lost by a vote of ninety-six to one hundred and fourteen.

DR. A. L. LOOMIS then moved that when the vote was taken on the adoption of the amendments it should be by ballot, and DR. AUSTIN FLINT, SR., moved as an amendment to this that the question of the adoption of the amendments be indefinitely postponed. The ayes and nays were called for on the amendment, and it was found to have been lost by a vote of ninety-five to one hundred and seventeen. A motion was then passed to proceed with the balloting on the question of the adoption of the amendments, and the chair appointed Drs. Nicoll, Lewis, and Jacobus tellers. The result showed one hundred and twenty-one votes in favor of the adoption, and ninety-two opposed.

DR. BARKER, after announcing that the amendments were defeated (having failed to receive a three-fourths vote), which he said he did with much pain and regret, remarked that he trusted that all bitterness and ill feeling would now be forgotten, and that all the members would henceforth devote themselves with renewed energy to the scientific work of the Academy, and to the development of its library.

DR. LOOMIS then offered a resolution to the effect that the resolutions of Dr. Austin Flint, Jr., which were adopted last spring, providing that every candidate for membership should be required to subscribe to the Code of Ethics of the Academy, should be rescinded. After he had made some remarks in favor of the resolution, DR. FLINT, JR., got the floor, and claimed that the motion was not in order, since it amounted to a reconsideration of the resolutions passed last spring, and at the time they were adopted it was voted that their reconsideration should be indefinitely postponed.

The CHAIR decided that Dr. Loomis's resolution was in order, and Dr. Flint, Jr., having appealed from this, the decision was sustained by the Academy. After remarks in support of the resolution by Drs. Roosa and Agnew, it was put to vote and carried, and the meeting adjourned.

The Academy is thus left in precisely the same position as regards the Code of Ethics as it was last spring before the adoption of Dr. Flint's resolutions. At this meeting both sides made every effort to secure as large an attendance as possible, and there were about 100 "old Code" men to 121 "new Code" men present. The result of the votes show a slightly less number of the former than this figure, but this was because Drs. Alonzo Clark, Frank Hamilton, and several other of the older men on that side were obliged to leave before the voting was reached on account of the lateness of the hour.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK. ANNUAL MEETING.

ELECTION OF OFFICERS.

IN consequence of the immense attendance at the ninety-eighth annual meeting of the County Medical Society, it became necessary to "hire a hall," as the ordinary place of meeting would have proved entirely too small. Accordingly the large hall of the Young Men's Christian Association, on the corner opposite the College of Physicians and Surgeons, was secured, and it was found when the votes were counted that no less than 599 ballots had been cast. The result was a decided victory for the "New Code" ticket; but the majority would have been nearly one hundred smaller had it not been that on the very night of the election there were elected over eighty new members, who, with possibly one or two exceptions, had been expressly brought into the Society for the purpose of casting their votes for this ticket. A motion to lay the election of these new members on the table until after the election of officers, which was made by Dr. A. Flint, Jr., was voted down by the New Code party.

Dr. Van Der Poel received a majority of 155 votes over Dr. Thomas, the candidate for President of the "Old Code" side, and the entire "New Code" ticket was elected, as follows:—

President, Dr. S. Oakley Van Der Poel; Vice-President, Dr. Andrew H. Smith; Secretary, Dr. Wesley M. Carpenter; Assistant Secretary, Dr. Charles H. Avery; Treasurer, Dr. Orlando B. Douglas; Censors, Drs. F. R. Sturgis, David Webster, Daniel Lewis, F. R. S. Drake, and Joseph W. Howe. Brevet Lieut.-Col. Bennett A. Clements, Surgeon United States Army, now stationed in New York, was elected an honorary member of the Society, and two amendments to the By-laws were adopted. The first was in reference to some details in the application of candidates for membership, and the second was as follows: "No member of this Society shall assume any sectarian designation indicating that his practice is based on any special doctrine or dogma, or specified method of treatment."

At one time during the evening something of a sensation was created by the inquiry of one of the members, Dr. Oberndorfer, whether bribery were sufficient ground for challenging a vote in the election. If such were the case, he said, he was prepared to challenge the votes of all the new members. He afterwards explained that he did not mean to impeach any of these gentlemen, but that he had positive proof in his possession that a certain member of the Society had attempted to

use bribery in inducing a physician (not a member) to join the Society in order to vote for one of the tickets that was up for election.

On motion of DR. F. R. STURGIS the matter was referred to the *Comitia Minora* with full power to investigate.

EXPULSION OF DR. H. H. KANE.

In accordance with a recommendation of the *Comitia Minora*, Dr. H. H. Kane was expelled from the membership of the Society by a unanimous vote. Charges had been preferred against him for publishing a work of improper character on spermatorrhœa, the opium habit, and similar subjects, and these had been referred to the Committee of Ethics, who summoned him to appear before them. He refused to do this, but an investigation was made which left no doubt of the truth of the charges.

TREASURER'S REPORT.

From the report of the treasurer, DR. O. B. DOUGLAS, it appeared that the receipts of the Society during the year had been \$3660, and the disbursements \$3668.50; while the balance remaining in the treasury was \$235.43.

ETHICS.

The Committee on Ethics, DR. CHARLES S. WARD, chairman, reported that but three cases had come before them since the last annual meeting. One of these had been disposed of by arbitration, and the other two had been referred to the *Comitia Minora*.

PRIZE ESSAYS.

DR. A. E. M. PURDY, from the Committee on Prize Essays, reported that but one essay had been presented, and that the merit of this had not been deemed sufficient to entitle it to the award of the prize. Its subject was, Tubercles of the Breast.

REPORT OF BOARD OF CENSORS.

The report of the Board of Censors, which was read by the secretary, DR. H. B. CONRAD, showed that the Board had been steadily carrying on the work of causing compliance with the law of 1880, and that it had also succeeded in the important undertaking of closing a bogus school, the United States Medical College. This institution had been successfully prosecuted in two courts, and, owing to the representations which had been made to him by the Board, the Governor had promptly vetoed a bill passed by the Legislature to confer a charter upon it. It had been demonstrated beyond question that the law of 1848, under which it claimed a legal status, never contemplated the establishment of medical colleges at all, and that in the State of New York medical colleges did not come under the head of benevolent and charitable institutions. The report recommended, in conclusion, that the law should be amended so that all those coming to New York from other States to practise medicine should be required to pass an examination, whether they had diplomas or not. At present the only requirement for registration as practitioners for those holding diplomas is that the latter should be indorsed by some legally constituted medical college.

The report of the counsel for the Society, EDWARD C. RIPLEY, Esq., was appended to that of the Board of Censors, and in it he gave a résumé of the prosecutions continued or begun during the past year. In no class of cases, he said, were there so large a proportion of convictions secured as in those brought into the courts

by the Censors of this Society. In some instances, however, the course of justice had been thwarted by unprincipled parties, and the conduct of the New York Eclectic Medical College had been particularly disgraceful in this respect. In no less than five cases had this institution indorsed the diplomas or licenses of notorious charlatans while they were actually being prosecuted for practicing illegally, and thus put an end to the proceedings.

THE GRANTING OF MEDICAL DIPLOMAS.

The following communication from the West Chester County Medical Society was read and referred to the *Comitia Minora*:—

WHITE PLAINS, NEW YORK, September 26, 1883.

DR. W. M. CARPENTER, Secretary Medical Society of the County of New York. — At the annual meeting of the Medical Society of the County of West Chester in June last, the Board of Censors presented the following resolutions, which were adopted:—

Resolved, That the representatives of this county in the State Legislature be requested to urge the passing of an act to prohibit all medical colleges from granting diplomas, and requiring all candidates for the degree of Doctor of Medicine to appear before a State Board of Medical Examiners, who shall recommend successful candidates to the Regents of the State University for a diploma.

Resolved, That the secretary send a copy of this resolution to the members of the Legislature from this county, and to every County Medical Society in the State, and urge them to take the same action.

We think this resolution expresses the universal sentiment of a profession crowded with those who have virtually bought their diplomas. Let us earnestly coöperate to obtain the desired legislation. Please inform me of the action of your Society.

N. F. CURTIS, Secretary.

DR. JOHN C. PETERS, chairman of a committee to investigate the subject of

SCARLET FEVER IN HORSES,

then made a report. He said that the committee had been appointed only in April last, and, consequently, had had but little time to do much satisfactory work; but he believed that there was no kind of doubt that scarlet fever did exist among horses, that it had done so from time immemorial, and that it was at present to be found among the horses of the city of New York. Its diagnosis, however, was apt to be attended with great difficulty, and many veterinary surgeons, among whom was Dr. Liantard, a member of this committee, denied the possibility of its occurrence. Still, the great weight of authority on veterinary medicine was in favor of its existence, and Dr. Peters quoted from an elaborate work by Robertson. The reason that so few cases of the disease were seen, he continued, was because almost all horses suffered from it in their youth, at the time of their first exposure to the bad hygienic conditions of large stables, where the true nature of the affection was not recognized on account of its being masked by the more pronounced symptoms of other disorders contracted and occurring at the same period.

In modern times the first to call attention to scarlatina in horses was Dr. Percival, a noted veterinary authority, who wrote in 1834. Dr. Copeland, the author of the well-known medical dictionary, had then taken up the subject with enthusiasm, and as the result of his investigations stated that it was a modern disease, which originated in the horse and had been communicated from the horse to man. It had now been conclusively demonstrated, Dr. Peters went on to say, that the first mention of scarlet fever in

horses was in 1514, while the first mention of its occurrence in man was not until nearly a century later, in the year 1610.

The next point to determine was, could the virus from the horse when affected with scarlatina be used to protect the human subject from the disease? Dr. Stickler, to whom the profession was indebted for calling attention to this important subject, was, he believed, on the eve of establishing that such was the case; and he hoped himself to live long enough to see inoculation as a protection against scarlet fever as commonly practiced as vaccination. Dr. Stickler had for some time been successfully experimenting with young colts. In conclusion, he trusted that the Society would devote some attention, at least, to the subject, and would do what it could to uphold the hands of Dr. Stickler, who was sure to meet with plenty of indifference and opposition in his work. On motion of Dr. Peters, the committee on this subject was increased to five, with power to accept resignations and fill vacancies.

So large was the number of votes cast, and so long did it take the tellers to count them, that it was considerably past midnight when the result of the election was announced and the Society adjourned.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

C. B. NANCREDE, M. D., RECORDER.

THURSDAY EVENING, September 13, 1883. The President, DR. TYSON, in the chair.

SPECIMEN OF VERY LARGE ULCER OF THE STOMACH, WITH UNUSUAL FEATURES.

Presented by CHARLES W. DULLES, M. D.

The specimen which I have to show you came from the body of a patient of Dr. Edward L. Anderson, who had had Dr. J. H. Musser to see her in consultation during life, and who asked my assistance in making the post-mortem examination, because of Dr. Musser's temporary absence from the city. To the clinical notes of Dr. Anderson, and my notes of the autopsy, Dr. Musser will, no doubt, add his own impressions of the case, which has appeared to me to be of singular interest and instructiveness.

The following are Dr. Anderson's notes:—

Mrs. M., aged thirty-five years; her husband living; the mother of five children, one of whom died of stricture of the pyloric or cardiac end of the stomach. Both her parents died before their fiftieth year.

May 12, 1883, at my first visit she was confined to bed, and stated that since the birth of her last child she had not been well, having more or less dyspepsia, and growing steadily worse for the last six months. She complained of a constant burning pain in the region of the stomach which nothing seemed to relieve. She vomited daily, sometimes immediately after a meal, but oftener not until evening, when it seemed to her all the food she had taken during the day would be ejected. The matter vomited was intensely sour, dark, and frothy, having the appearance of yeast. There was always pain after vomiting, and at all times irregular pains over the abdomen. She was anæmic, emaciated, and had a weak but regular pulse. Upon physical exploration I could find no tumor. Her heart and lungs were normal, and, as I afterwards learned, the

urine likewise. The abdomen was resonant. She was placed on a milk diet, with pepsin and ten drops of sulphurous acid every three hours. She took two quarts of milk daily, and did not vomit until the 22d of May, — a period of ten days. On this day she vomited but a small quantity of food.

May 23d, the period of her menstruation (though not menstruating from April until the time of her death), she ate, on her own responsibility, a fritter for supper. This indiscretion brought on an attack of vomiting and sufficient prostration to cause considerable alarm to her family and cause them to send for me. I found her much exhausted, only able to speak in monosyllables, with a pulse of 104, and respiration 40. She complained of intense, burning pain in the stomach. External heat and sulphurous acid internally gave relief. This was the first time I was able to see the vomited matter, and I found it to be digested blood, about two quarts in amount. Dr. J. H. Musser kindly examined the material microscopically and found blood corpuscles, pus globules, and epithelial cells. I was told she had vomited similar material prior to my first visit. The vomiting was repeated on May 25th, 26th, 27th, and 28th, and several times there were free hæmorrhages. She was treated with bismuth and carbolic acid, with enemata of milk, whiskey, and eggs, and inunctions of cod-liver oil. Hæmorrhages occurred again on June 6th, 7th, and 8th. On June 10th Dr. J. H. Musser saw the case in consultation. He thought he detected a tumor. We came to no positive diagnosis, but wavered between carcinoma and ulcer. It was only when the patient was placed in the knee-elbow position that a tumor could be felt, and this a little to the right of the median line. The treatment was changed to one drop of hamamelis every twenty minutes, and a pill, containing one fourth of a grain of oxide of silver, three times daily. June 17th and 18th hæmorrhages again occurred; but from this time until her death, about six weeks later, there were no more hæmorrhages, little inclination to vomit, and very little pain. This was notwithstanding the fact that I have reason to believe that for about a month before her death she paid no particular attention to her diet, while the only part of the treatment carried out was the taking of the oxide of silver pill. About three weeks before her death a troublesome cough set in, but it was easily controlled by opium. Her death followed a large meal and free draughts of coffee and water. The act of death was quiet and gradual, entirely unaccompanied by pain or alarm.

The notes of the autopsy are as follows:—

September 2, 1883. Body of Mrs. M.; aged thirty-five; thirty hours after death, rigor mortis absent, body much emaciated, right hand puffy with œdema, bruise over middle of right shin. Examination of thorax, abdomen, and pelvis.

There was no fluid in either pleural cavity. Both lungs were attached, at the upper part, to the parietal pleura by adhesions which broke down easily. The upper lobe of each lung was pretty well solidified with chronic catarrhal deposits, quite soft. In each upper lobe there was a cavity. That in the right lung was as large as a hen's egg, that in the left about the size of a pigeon's egg. Both were ragged and contained dirty grayish detritus. The lower lobes of both lungs contained a number of small nodules of caseous degeneration.

The heart was very small and firm, about the size of

a goose-egg. Its valves were normal, and it contained but a small quantity of fluid blood in its right cavity.

The abdomen contained about a third of a pint of slightly turbid serous fluid. There was not the slightest injection of the peritoneum anywhere, nor any other evidence of peritonitis. The pelvic organs were all normal in appearance, except the uterus, which, though of normal size, was in a state of marked retroflexion. The bladder contained about two fluid ounces of urine. There was no omental apron. The liver was of normal size and appearance. The gall-bladder was normal in appearance, and contained about half a fluid ounce of saffron-colored bile, but no gall-stones. The spleen was normal. The kidneys were of normal size, rather hard, their capsules adherent, their surface a little granular. On section their cortex was found somewhat diminished. The supra-renal capsules were very tough, the right more so than the left. The pancreas was of normal appearance at its left end, but at its right it was attached to the stomach, and was decidedly indurated. Here it was imbedded in a quantity of delicate adhesive bands, which united into a bundle its own duct, the end of the ductus communis choledochus, and the pyloric end of the stomach. The intestines were collapsed and empty, except the duodenum, which contained a small quantity of thick bile-stained chyme.

The stomach itself presented the features of the greatest interest. It was much enlarged by dilatation, its walls were thin and pale, its vessels along the greater curvature much enlarged and full of dark blood. It occupied a slanting position, from above downwards and from left to right. It contained about *two quarts* of grumous, sour-smelling, fluid ingesta, and with this it was not nearly filled. At the upper part of the pyloric entrance it bore a firm puckered induration, looking like a cicatrix, about two thirds of an inch in diameter. Close by this was a large ulcer about two and a half inches long, and over an inch wide, with indurated, thickened, and in part perpendicular, edges. This ulcer passed through all the coats of the stomach. Nevertheless the large quantity of fluid contents of this viscus had not escaped from its cavity, because the ulcerated part of the stomach was applied against the adjacent pancreas and attached to it by adhesions. This attachment, however, was extremely delicate, and would not bear the gentlest handling. It gave way while the viscera were still in the abdomen upon an attempt being made to lift the pancreas up while the stomach was held aside. This disclosed what seemed to be a loose connective-tissue mesh between the stomach and pancreas, in which a small quantity of the ingesta was found.

The pyloric orifice of the stomach was at the edge of the induration surrounding the ulcer, and it was so contracted as to barely admit the passage of a grooved director through it.

CASE OF TUBERCULAR ULCERATION OF THE INTESTINE, WITH TUBERCULAR INFILTRATION OF THE LUNGS AND SPLEEN.

E. H., aged forty-three, married, was admitted to the Episcopal Hospital July 16, 1883. The following notes were taken by DR. GEORGE M. BOYD, the resident physician. The patient states that she has been sick since last April. Her trouble began with vomiting and purging, which it seemed impossible to check. No cough was complained of, and there appeared on admission to be no marked dullness on percussion over

either lung, but in consequence of the patient's statements a careful physical examination of the lungs was not made. She was very pale and much emaciated. At first almost all nourishment was rejected, but after a few days the stomach became more tolerant of ingesta. Pain was complained of in the left inguinal region, where there seemed to be an undue degree of fullness, but the pain was relieved by poulticing, and the diarrhoea was relieved to a certain extent by opium and astringents. Four or five thin, dark, and watery passages occurred every twenty-four hours in spite of treatment. Sometimes small clots and shreds of coagulated blood were seen in the passages.

The diarrhoea became again more profuse and the emaciation more extreme. About a week before her death patient began to complain of cough, and auscultation then revealed tubular breathing and gurgling below the right clavicle.

Death occurred on August 30th.

The post-mortem examination was made fifteen hours after death. Rigor mortis hardly yet well established. The body is extremely emaciated; the omentum being almost destitute of fat.

Heart. Weight four ounces; tissue pale.

The apices of both lungs present numerous cheesy nodules, with catarrhal pneumonic thickening. The right lung presents at its apex a cavity with smooth walls of the size of a pigeon's egg.

Spleen. Weight two and a half ounces; its section shows numerous cheesy nodules.

Left kidney. Weight two ounces; capsule adherent, and cortex diminished.

Right kidney, weight four ounces.

Liver fatty.

Small intestine almost empty and contracted; its mucous surface is everywhere injected, and about eighteen inches from the ileo-cæcal valve it presents two or three small round ulcerations, which do not penetrate quite to the peritoneal investment. Mesenteric glands everywhere swollen and veins dilated.

The large intestine presents throughout its entire extent thickening of its submucous layer and other indications of chronic inflammation. The inflammation has caused in the descending, and a portion of the transverse, colon complete, or almost complete, destruction of the mucous membrane for a space of about three feet. The muscular layers are thickened, and the mesenteric glands swollen, and there is some thickening and undue opacity of the walls of the vessels, but no tubercular granulations can be detected with the naked eye.

CASE OF CANCER OF THE LIVER.

The patient, S. A., aged sixty-five, single, was admitted to the Episcopal Hospital July 31, 1883.

The following notes were made by Dr. Claxton, the resident physician: While at work, six weeks ago, the patient began to experience pain in the epigastric and right hypochondriac regions. Two weeks later he noticed that he was jaundiced, and that there was a lump (or swelling) in his abdomen.

Upon admission to the hospital the patient was much emaciated, and very feeble; skin and conjunctivæ intensely jaundiced, of a deep saffron hue.

There was marked bulging noticed in the right hypochondriac and epigastric regions. The tumor, which could be plainly felt through the thin abdominal wall, was found to extend four inches below the xiphoid

cartilage, and two inches to the left of the linea alba. The mass occupying the right hypochondriac region was found to be distinctly nodulated, and very hard. Some of the nodules appeared to be umbilicated. The patient presented a markedly cachectic appearance; tongue thickly coated with a dirty yellowish-brown fur; his bowels were constipated, and there was anorexia.

Purgation failed to influence the size of the tumor. The patient complained of insomnia, but did not seem to suffer much. Mental action was sluggish. The patient became rapidly weaker, and for fully a week before his death it was noticed that his extremities were very cold, and fully three days before his death his pulse had become so weak as to be almost imperceptible. Death finally occurred on August 16th.

The post-mortem examination was necessarily a hasty one, as the body was removed from the hospital within two hours of the patient's death.

The new growth appeared to involve, however, only the liver and the pancreas. The common bile duct was completely occluded by a hard nodular mass which had its apparent origin in the pancreas. Above the occlusion the cystic duct and the gall-bladder were distended with dark olive-green bile.

The liver weighed five pounds six and one half ounces. Section of the organ showed complete infiltration with cancer nodules, and little or no normal hepatic tissue could be seen.

The spleen was markedly atrophic, weighing one and one half ounce.

The kidneys were deeply stained with bile, and seemed somewhat contracted.

The heart was very small, and its muscular tissue flabby.

Recent Literature.

Hand-Book of Electro-Therapeutics. By DR. WILHELM ERB. Translated by L. PUTZEL, M. D. New York: William Wood & Co. 1883. Pages xiii., 366.

This is one of the volumes of Wood's Library of Standard Medical Authors. It is scarcely necessary to say that the author is one of the best authorities on the use of electricity in diseases of the nervous system. We should, therefore, expect a correct work; the present book is also practical and simple. The physical and physiological introductions, to which the first six lectures are devoted, require only fifty-seven pages, are concise, and give what is most important for the student to know. The lectures devoted to electrical examination and electro-diagnosis are in part familiar to us in connection with the eleventh volume of Ziemssen's *Cyclopædia*, but the subject is considered more fully, as in connection with the nerves of special sense, naturally most of that lecture being devoted to the auditory nerve.

Under the title of General Electro-Therapeutics the value of electricity as a therapeutic agent, the various modes of applying it, and certain precautions, are given; then follows the part devoted to Special Electro-Therapeutics.

A few subjects often found in treatises on electricity are omitted. Nothing is said in regard to the application of electricity to surgery. Static electricity is only briefly mentioned as not having furnished very en-

couraging results, and that it "has still to conquer a secure place in electro-therapeutics." Of electric baths he says, "*A priori* it cannot be denied that the electrical bath may produce very marked effects, but the therapeutical experiences hitherto obtained are not calculated to inspire faith in its efficacy. It appears to have been most successful in certain forms of tremor, especially mercurial and alcoholic tremor, then in chronic articular rheumatism, in cerebral neurasthenia."

Of "general faradization" he says, "I have employed general faradization with sufficient frequency to satisfy myself of its decidedly favorable effects." He does not speak so warmly of "general galvanization" and "central galvanization."

The translation is well done, but in giving the formulæ for the electrical reaction of nerves and muscles the German has been translated, which gives a somewhat confusing combination of Cs. We have Ca, Cl, C, to represent the cathodal closing contraction. When, however, Ohm's law is given, the formula $I = \frac{E}{w + r}$ is used, W and w denoting the essential and the extra essential resistance. A translation into R and r would have been consistent.

L'Année Médicale (cinquième année) 1882. Résumé des Progrès Réalisés dans les Sciences Médicales. Publié sans la Direction du DR. BOURNEVILLE. Paris: E. Plon & Cie. 1883.

L'Année Médicale of Dr. Bourneville is sufficiently well known to need no especial description. The usual number of competent collaborators have taken part in preparing the present volume, and the usual plan has been followed.

It strikes us that the year 1882, with which this number deals, is rather less marked by interesting or important medical novelties than is often the case.

A Practical Treatise on the Medical and Surgical Uses of Electricity, including Localized and General Faradization, Localized and Central Galvanization, Franklinization, Electrolysis, and Galvano-Cautery. By GEORGE M. BEARD, M. D., and A. D. ROCKWELL, M. D. Fourth edition. Revised by A. D. ROCKWELL, M. D. New York: William Wood & Co. 1883. Pages xxx., 758.

It is only necessary to call attention to this book, which has been noticed when the previous editions appeared. This fourth edition is the same as the third with the addition of a few pages upon franklinic or static electricity, and a few pages in regard to extra-uterine pregnancy.

The Essentials of Pathology. By D. TOD GILLIAM, Professor of Physiology, Starling Medical College. P. Blakiston, Son & Co. Philadelphia: 1883. 296 pages.

In this book an attempt has been made to condense and render attractive a very extensive subject, and the task has been found a difficult one. A great many old names have been retained which referred to the general appearance of diseased organs simply, without reference to the process by which such changes are pro-

duced. There is also a frequent tendency to describe the symptoms observed during life, in fact to give the history of the disease, rather than appearances and their cause. It may possibly be of service to a certain class of students, but hardly contains the systematic fundamental teaching which is to be regarded as the essential of pathology.

Medical and Surgical Journal.

THURSDAY, NOVEMBER 1, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

HOUGHTON, MIFFLIN AND COMPANY,

NO. 4 PARK STREET, BOSTON, MASS.

THE MEDICAL TEACHING OF THE FUTURE IN BOSTON AND AT THE HARVARD MEDICAL SCHOOL.

THE beginning of a new century of life and the completion and opening of a new and admirable building have given the Harvard Medical School an opportunity to call its friends, neighbors, benefactors, and prominent professional men from various parts of the country together to tell them what it has done in the past in the cause of medical education, to show them what it is prepared to do in the present, and to receive their congratulations. These have been extended in no reluctant spirit by those who were fortunately able to be present at the late ceremonies. And the full and appreciative accounts of the recent occasion contained not only in the columns of the JOURNAL and the local daily newspapers, but also in those of the other medical periodicals in larger medical centres, have practically increased many fold the number of those ready to hear and see what Harvard has to say and has done in this important cause.

Dr. Holmes sketched in his inimitable address the history of the School from its infancy, and the changes in the methods of education during the last generation. Although the festivities are still fresh in mind, and the congratulations have scarcely died away, it seems not only neither premature nor ungracious but rather a suitable moment to ask what is the tendency of the present methods, what are the weak points, — if any, — what directions the changes in medical education are likely to take in the next generation, if it is possible to forecast them. Admiration and approval of what has been done have been too warm and spontaneous to allow speculation as to what may be done to seem other than friendly.

Some of the directions in which changes will take place within the next generation are already clearly indicated. It requires but a slight acquaintance with the principal medical schools of the country to see that they have grown greatly from their small begin-

nings, and that they are by no means at a stand-still. Progress, though sometimes an irregular and uneven progress, has been the rule, and the graduate of to-day is very different from the newly-fledged M. D. of a generation ago. To confine our remarks, however, to Harvard, we may say in the first place that changes are already discussed in courses preliminary to a medical education which will have great influence upon the Medical School. The preliminary study of another generation will unite what is best in the present academic and technological schools. Modern languages will undoubtedly be more prominent; the student will enter better trained in the natural sciences; general chemistry will be relegated entirely to the preliminary course; something real will be required in comparative anatomy, botany, and physics. Not a little time will thus be gained, perhaps a full year, and the fourth year (then becoming relatively a fifth year), which is now encouraged but not required, will be an established portion of the curriculum, and in it we may see a system of electives which shall allow some choice in the study of specialties. The condition of the School itself will, we confidently believe, be entirely changed by the possession of a fund large enough to make it to a considerable extent independent of fees. Perhaps no school acts as independently to-day towards its students as does Harvard, but a great gain should take place when such independence actually exists. The establishment of scholarships will assist in maintaining a high standard, and graduate fellowships will allow the special training of men to teach in the more strictly scientific branches.

Thus much of the promised land we are permitted and encouraged to see with a certain sharpness of outline, but with the eagerness of the explorer we desire to enlarge still farther our horizon, to see dispelled the mists which veil certain features in the outlook. The new building of the School emphasizes more particularly a provision for laboratory work, the development of what are regarded as preliminary courses, the broadening and deepening of the foundation upon which the education of the physician is to be reared. The present method of class instruction is already strong, where the old apprenticeship system was weak, in the attention paid to preliminary and to laboratory work. But a school in which the influence of laboratory men is strongly felt naturally exalts still further the scientific, though a physician trained in scientific methods must still deal with the uncertain. Years ago students looked on while the professor of anatomy dissected; they looked on while the professor of chemistry did or attempted brilliant experiments; too often they still look on while the professor makes a diagnosis or prescribes. The present method of class instruction — especially as shown to exist at Harvard in a paper by Dr. E. N. Whittier recently published¹ — is greatly superior as a whole to the old apprenticeship system, but in one respect it greatly falls behind that almost obsolete system, that is in the failure to bring the great body of students into close relationship with the sick, and it is in this direction that

¹ JOURNAL, vol. cix., p. 289.

changes are most to be expected and most to be desired. Such changes are already taking place. Year by year new places are thrown open to students where they can see and examine patients themselves in return for such services as they are able to give, but this takes place in a somewhat desultory and uncertain fashion. The Faculty now recognize the necessity of making each student familiar with disease; we expect they will rise to the necessity of making each and every one familiar with the sick. At present a student who early desires to see clinical work, and is helpful and agreeable, will find abundant opportunities; and to their credit be it said a very large number seek these opportunities; they feel that they are in training for their life work, and they go about it in earnest, but some who are diffident or indolent see very little. The best men, or the most fortunate, get a training that leaves little to be desired, but it is pitiful to think how small an amount of actual experience in the care of the sick a man may have and still graduate. Time was when a man could receive his degree with only a theoretical knowledge of midwifery; that time has happily gone by. No man can graduate who has not given some practical evidence of a certain familiarity with at least some forms of disease, but the facilities for obtaining such familiarity are defective.

The chief improvement of the next thirty years will consist in reducing the clinical teaching to a system similar to that pursued in the chemical laboratory. We do not venture to predict precisely how such a system will be brought about, but it will unquestionably necessitate a more intimate union with the hospitals and dispensaries, and various ways of promoting such an end readily suggest themselves. An appointment to a hospital might be made to carry with it the obligation to give clinical instruction, the system of continuous hospital service which bears such good fruit in Europe, and which is finding favor in New York, might be introduced; such steps depend upon the favor of hospital trustees. A school may have its own hospital, as is the case with the London schools, but in such a relationship, as a rule, the hospital comes first and the school springs from it, and very large endowments are needed. It is, we believe, through the encouragement and development of extra-mural teaching, so effective in Edinburgh, in Germany, and at the Italian Universities, that we might rationally anticipate a favorable solution of the question of clinical instruction in the future at the Harvard School. It has ceased to be a school of one teacher in each branch; it has ceased to be a school of one hospital; to put clinical teaching where it ought to be it is quite time for further progress in the same direction. One school is quite enough to dispense degrees, but there cannot easily be too much clinical teaching or too many teachers. Not in *graduating* but in *teaching* students competition breeds excellence, and in this way the stimulation of two schools may be had without the evils. By far the larger part of the clinical material in Boston is still unused even during the regular educational months, and it is only within a very few years that any educational advan-

tage has been drawn from patients during the summer months, but the efforts in this direction are appreciated by students, although entirely independent of the School. Again, by extra-mural teaching not only are the advantages of the old apprentice system preserved and the student in small classes is brought into close contact with the patient and the instructor, but a large number of teachers are constantly in training from whom the School may choose future professors. The continued expansion of the City Hospital, the erection of an ample and well planned building on the grounds of the Massachusetts Hospital for its out-patient services, the commodious and convenient structure just opened by the Boston Dispensary, offer unaccustomed facilities, and even entail upon those holding appointments obligations for increased and varied clinical teaching. The School should not only recognize but we hope will encourage this, and another generation will see a great advance in the department which must always place the crown upon the medical student.

If we intimate that improvement is possible we do not fail at all to appreciate the improvements which have been made.

In teaching midwifery we have little doubt great changes will be made — approaching more nearly the continental systems — which must await the development of lying-in hospitals.

We confidently hope also to see some new method introduced in the study of therapeutics that shall put it in some way upon a par with the study of physiology, so as to put an end to the loose methods of drawing deductions as to the operations of drugs upon the animal economy, which the School already has done so much to correct.

We shall not be surprised to see more careful study of the diseases of animals contribute to the instruction of medical students. Comparative physiology is recognized as a necessary portion of the study, perhaps the basis, of human physiology; comparative anatomy is an important adjuvant in the study of human anatomy; comparative pathology and comparative therapeutics have not yet been given a similar importance. That they will reach it some time seems inevitable, whether in the next forty years is not quite so certain.

To condense our remarks, we believe something of the same practical methods will be introduced into the teaching of general practical knowledge as are now employed in teaching the preliminary and scientific branches, while not only scientific medicine but practical medicine also in its special divisions will be still further fostered by post-graduate courses.

— "Mr. George N. Chipman, in attempting to lift a huge rock, sprained the *semi membra nosis* of his left leg, causing him to be confined to his home for about a week. We are pleased to say that Mr. C. has recovered and about his business." — *Lay Exchange*.

— Tar beer for chronic laryngeal and laryngobronchial affections is used in great quantity at the Philadelphia Polyclinic.

THE STATE ALMSHOUSE AT TEWKSBURY.

THE annual report on the State Almshouse at Tewksbury, Massachusetts, for the year ending September 30, 1883, has been sent to the Governor by the Board of Health, Lunacy, and Charity, which has acted as trustees since April 28, 1883. It is accompanied by the report of the Superintendent, Dr. C. Irving Fisher, who has only been at the institution about three months. Dr. Fisher's report covers two months of his own service, and that of the Board five months of its control. The report of the Board is signed by all the members, by the appointees of the present Governor of the State, as well as by the others. Both reports are concise, business-like documents, and should be satisfactory to all citizens interested in the welfare of our State Charities but who do not think they are proper playthings for politicians and much less for demagogues.

Various minor changes have been introduced into the general management of the asylum, the most important of which we believe to be that able-bodied paupers are compelled to labor during their period of residence.

Tewksbury is, in fact, really a hospital rather than an asylum, which suggested the propriety of placing a medical man in the position of superintendent. Of the inmates Dr. Fisher says:—

"Looking at these people from the stand-point of health, we find three classes,—the sick, those in the hospitals, the feeble and deformed, not requiring hospital treatment, yet unable to work, and the well. The two latter classes are mingled during the day and occupy the same wards at night; hence the line of division cannot be distinctly drawn, and the well are constantly managing, under false pretenses, to get rid of the work which might properly be required of them. If the able-bodied are to be supported here, the force of officers should be sufficient to make them do a reasonable amount of work.

"The statistics show that there have been admitted during the year 3231. There have been supported during the year 3170, the weekly average being 956, which is 61 more than the weekly average of last year. This is due in a measure to the burning of the State workhouse."

Admission has been denied to motherless infants since October, 1879. "The hospital statistics," the report goes on to say, "show that there have been 1980 cases treated during the year, which is 321 more than appear in the tables of last year, an increase of nineteen per cent. There have been 233 deaths, which is two less than the previous year. Of these, 16 were of the insane. There have been 20 more births than last year. Considering the rapidly increasing number of patients it becomes apparent that our great and pressing need is more hospital accommodation. The wards are crowded far beyond the sanction of medical judgment. In the male hospital, because of its arrangement, we are obliged to classify patients according to their loathsomeness and excitability rather than according to their diseases. We have no wards which admit of proper isolation of

patients. Many men are now obliged to sleep in the dormitories and eat the ordinary house diet who ought to have hospital care and food. A new building is needed, and should be planned with reference to the proper separation of certain classes of disease. The present building could then be used as a convalescent ward, and would need but few changes. If a new hospital is built it might be so placed as to inclose, with its connecting corridors, a yard where the patients could be by themselves, not subject to the annoyances and temptations which come from contact with the able-bodied. There is a large number of men and women who, by reason of age or deformity, go up and down stairs with difficulty, and the present arrangement of buildings does not allow a satisfactory removal to a ground floor. Whenever changes are made this is an object which should be considered. It would be well if something in the way of entertainment could be provided for the sane and insane. This would not only tend toward happiness and contentment in the lives of these unfortunates, but would bring the officers into social relations, and develop a sympathy with one another and a kindly feeling toward the inmates, which would increase their efficiency as officers."

The adoption of such suggestions requires, not a withholding of present appropriations, or a scaling down of future ones, or even a lot of bombastic declamation, but increased expenditure of money on the part of the State and of time on the part of the resident officials. The arrangement which the Board found existing for the disposal of the unclaimed bodies of deceased inmates was in conformity with the law on the statute books, but some improvements have been brought about in the details of the system. Owing to perfected methods of refrigeration it is found feasible to prolong the time accorded for the possible reclamation of a body; delivery of unclaimed bodies in future will take place at the asylum itself, to which institutions receiving bodies for the purposes of medical instruction will be required to return the remains.

The Board justly states that the management of any State institution will always be found susceptible of some improvement, but that any serious defects in that of the Tewksbury Almshouse had been remedied prior to the beginning of the present year, and that very few of the charges subsequently made against its conduct were in fact true.

These reports tell us what Tewksbury requires as an almshouse and as a hospital, and recommendations are made to satisfy these requirements; the reelection of the present supreme executive officer of the State is not one of them, nor does the representation of Massachusetts at the late Conference of Charities at Louisville lead us to regard the omission as unfortunate.

— The quarantine officer at San Francisco is quarantining every vessel arriving in port having a leper on board. The vessel is released only upon the captain's giving a bond undertaking to return such leper.

MEDICAL NOTES.

— All the world's a clinic,
And all the men and women merely patients.
They have their exits and their entrances,
And one man in his time plays many parts; . . .
His acts are more than seven ages.

Viewed through the professional opera-glasses of a contemporary the strange, eventful history is as follows:—

First year: icterus neonatorum, hyperkinesis intestinalis, and vaccination. Second year: dentition, croup, cholera infantum, and fits. Third year: diphtheria, whooping-cough, and bronchitis. Fourth year: scarlatina, worms, and meningitis. Fifth year: measles. Now half the children are dead. Seventh year: mumps. Tenth year: chorea and typhoid fever. Fifteenth year: hyperæsthesia sexualis. Sixteenth year: spermatorrhœa, chlorosis, and spinal irritation. Eighteenth year: blenorrhœa urethralis. Twentieth year: bubo, alcoholic cephalalgia, vertigo. Twenty-fifth year: matrimony. Twenty-sixth year: insomnia de infanto. Thirtieth year: dyspepsia, nervous asthenia. Thirty-fifth year: pneumonia. Forty-fifth year: lumbago, presbyopia. Fifty-fifth year: rheumatism, alopecia. Sixtieth year: amnesia, deciduousness of teeth, bony arteries. Sixty-fifth year: apoplexy. Seventieth year: amblyopia, deafness, anosmia, general dyskinesia, atonic digestive tract, rheumatismus deformans. Seventy-fifth year: finis.

— At the annual meeting of the corporation of the School for the Feeble Minded, the former officers were reelected as follows: President, Samuel Eliot; Vice-President, Edward Jarvis; Treasurer, Frederick W. G. May; Secretary, W. Brandt Storer; Auditors, W. W. Swan, W. Brandt Storer; Trustees, Samuel Eliot, Samuel A. Green, John Cummings, Edward Jarvis, W. Brandt Storer, John D. Washburn. The reports of the trustees, of the treasurer, and of the assistant superintendent, were presented, giving the following facts: The number of children now present is 144, 89 boys and 55 girls, and the average present during the past year has been 139. There have been 61 applicants for admission, of whom 46 were admitted and the rest declined, chiefly on account of epilepsy. Epileptics are not admitted. The reports give, at some length, an account of the steady, but quiet, progress of the pupils. The farm at Medfield is a most important adjunct to the school. The large boys are employed upon it quite profitably to themselves and to the school. One item of this year's produce is 377 bushels of potatoes, and in another year the farm promises to furnish all the milk required by the institution. The laws concerning the school were materially changed by the last Legislature. Admissions are now required to be made through commitments by judges of probate in all cases where the parents cannot pay for support of their child, after the method required in the admission of lunatics to hospitals. Cities and towns are also required to pay for the support of those who have no kindred able to support them, while the State pays only for the support of those having no legal settlement. In speaking of the past and future growth of the school the report says: "We have, within the past six years, built and fur-

nished the new west wing to our buildings. We have bought our farm, stocked it, and have removed to it fifteen of our large boys,—a great relief to the school. We have carried 120 to 140 children, as against 80 previously. We have had no increase in the appropriation from the State. We have never, knowingly, admitted an unsuitable case. We have done nothing, except good work, to advertise the school, and it is to-day one of the least known of all the institutions of the State. Yet in these six years our numbers have increased from 80 to 144, while in the seventeen years immediately preceding the number had increased only from 70 to 80." The treasurer's report showed that about \$30,000 had been paid out, and although there was a small deficit caused by attempting to support more children than the appropriation would warrant, he presented a very favorable financial exhibit. The amount of the invested funds is about \$23,000. At a subsequent meeting of the trustees the resignation of Dr. G. G. Tarbell, assistant superintendent, was accepted after much reluctance on the part of the Board, and Dr. Asbury G. Smith was elected assistant superintendent.

— One hundred and eighty persons are ill and four have died in a town of the province of Saxony from an epidemic of trichinosis.

— We have received the initial number of *The Medical Student*, a new publication dated from New York, and intended for circulation among American medical schools in general.

Correspondence.

TRAINED NURSES. A CRITICISM.

MR. EDITOR, — Notwithstanding the incalculable advantages of the trained nurse over one of the old school, I have more than once been confronted with an emphatic criticism of the new school which seems to me to have much of justice in it, and for which I believe the present training in the hospitals is to be partially blamed. The criticism is this, that the trained nurses, with all their technical skill and admirable training in implicitly obeying the physician's orders, lack that minimum of culture, I will call it, and delicacy in dealing with patients of refinement and sensitiveness, which I should be inclined to regard equal in importance to their professional training, and perhaps of greater moment upon the welfare of their patients. I do not wish to be understood as making this as a sweeping criticism against all trained nurses, but it is one that has been made by patients and their friends, who in making it have unjustly condemned the whole class.

One of our great surgeons once made the remark that when he was sick he wished his physician to do something more than merely to look at his tongue and feel of his pulse; that at such a time he wanted a little sympathy; the *man* desired some attention as well as the body.

Besides all the science and skill of the modern day, there is still something more needed by the physician who would be acceptable to his patients, particularly those who have been carefully reared. He needs something of refinement and tenderness and culture; for besides dealing with a diseased lung or an

injured limb as a problem involving mere science and skill, he is also dealing at the same time with a human entity of delicate nerves and acute feelings, yearning for a bit of sympathy. He is bound to recognize the psychic as well as the physical needs of his patients. So it is to a lesser degree with regard to the nurse; her patient expects something more of her in the way of refinement and tenderness than she does of her cook or her chambermaid, and yet I know of a case not long ago where the trained nurse when off duty affiliated with the kitchen girl. Moreover there is often a kind of roughness and disagreeable abruptness in the trained nurse which I suspect is in part due to the hospital life and the constant having to do with the kind of patients one generally finds there, as well as the large number of them they are obliged to attend. A criticism, which by the way, can be made sometimes against the young physician just out of his service in the hospital. In this respect the hospital training is bad, and both doctor and nurse may unconsciously form the vicious habit.

If the criticisms I have made are just ones, is the defect in the training or in the class of young women who enter the training schools? I believe in both. If the position and standing of the nurse in the future is to approach that of the physician, as a doctor of large practice, and who has much to do with nurses, declared to me not so long ago, then the class of women who take up the vocation must be higher to begin with, possess more refinement and culture, be gentlewomen. As an illustration I would mention the Children's Hospital, the nursing in which is conducted by the Sisters of St. Margaret, all of whom are ladies of refinement as well as most devoted and skilled nurses; hardly has one entered the institution before he somehow experiences an indescribable influence of gentleness and refinement. The hospital training schools of to-day, it seems to me, are not altogether suited or suitable for women of this kind. Too much mere drudgery work is still required, although changes for the better have been made in this direction. For example, after one has well learned the making of a bed it is of no especial profit, that I can see, to make a dozen or more every morning; the time might much better be used in study or in administering a bit of sympathy to a poor sufferer. As it is now, the primary question asked those who intend entering the training school is, Are you very strong and capable of enduring the hardest work? This in itself shuts out often those who are strong enough for the legitimate offices of a nurse, and who may be best fitted for them. I take it that this is not so much the fault of the management of the training schools as due to a lack of means, which compels, for economy's sake, the combining of the two departments, the chamber work of the hospital, if I may so denominate it, and the legitimate nurse's work.

The training school of the future, it seems to me, will have its own proper building and teachers, and require only such duties in the hospital as are peculiar to the nurse; and in addition to the studies now pursued there shall be more emphasis laid upon the humanities of the profession. Tenderness, gentleness, delicacy of step and touch should be insisted upon as much as the ability to take the temperature correctly or give a subcutaneous injection.

Very truly yours, EDWARD O. OTIS, M. D.
BOSTON, October, 1883.

A NOTE FROM DR. KNAPP.

NEW YORK, October 21, 1883.

MR. EDITOR,—If I had thought that the remarks in my introductory address which you incriminate in your issue October 18th with so much spirit as justice might by anybody be taken for more than a campaign anecdote, I would certainly not have connected my name with them. But as this seems to have been the case I consider it my duty to offer you and all whom it may concern my sincere apologies. Seriously speaking, my words to a Boston physician on Boston doctors, ought not to have been said, for the following reasons:

(1.) They violate the rule of propriety which forbids making one's self the hero of one's own story.

(2.) They are unjust to the city of Boston, which is large and wealthy enough to reward skilled labor of every description. Its inhabitants are deservedly famous for the liberality with which they patronize all kinds of public institutions.

(3.) They are unjust to the physicians—in particular the oculists—of Boston, whose high reputation I heartily indorse, well aware that not only in this country, but in all, the best work in the science and art of medicine has often enough been done outside the metropolis.

If you think, Mr. Editor, the above lines worthy of a corner in your journal you will, by inserting them, oblige yours respectfully, H. KNAPP, M. D.

Miscellany.

DR. SAMUEL EATON FITZ. OBITUARY.

DR. SAMUEL EATON FITZ, of Roxbury, Mass., died on the 20th ult. He was born in Boston January 26, 1836. During the years from 1852 to 1855 he was clerk in the lumber and coal business. He afterwards prepared for college in the Chelsea High School, and in due time entered Harvard College, graduating in the class of 1882. In September of the same year he entered the Theological Seminary at Newton, Mass. During the war he served a considerable time in the United States Christian Commission; for three months in 1863 with the Army of the Potomac, and again with the Army of the James from May, 1864, to the close of the war. He then became agent for the Commission at Richmond, Va., for a time. He returned to his studies in the Theological School and completed them in 1866, but was never ordained. From September, 1867, to May, 1874, he was principal of public schools in Winchester and Worcester, Mass. He began the study of medicine at the Harvard Medical School in September, 1874, and took his degree in June, 1878. He served as surgical externe and house physician at the Boston City Hospital for eighteen months, ending July, 1878. Since this time he has been engaged in the practice of medicine in Roxbury. He had suffered for some years from valvular disease of the heart, and within the last few months renal symptoms had added themselves. He died from uræmic convulsions. He was never married.

Dr. Fitz was a man of singularly modest and unassuming character. But the few who knew him intimately found behind his quiet and retiring manner a kindly disposition and a well-stored mind.

Deaths reported 3535: under five years of age, 905: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 524, consumption 360, lung diseases 206, diphtheria and croup 176, diarrhoeal diseases 112, typhoid fever 79, scarlet fever 52, malarial fevers 47, whooping-cough 19, erysipelas 11, cerebro-spinal meningitis nine, measles eight, small-pox six, puerperal fever five. From scarlet fever, New York and Philadelphia 10 each, Boston seven, Chicago eight, St. Louis four, Baltimore, Buffalo, and New Haven three each, Brooklyn two, Cincinnati, Providence, and Lowell one each. From malarial fevers, New York 13, Brooklyn eight, St. Louis and New Orleans seven each, Baltimore five, Charleston three, Philadelphia two, Chicago and New Haven one each. From whooping-cough, New York four, Brooklyn three, Baltimore and New Orleans two each, Chicago, Boston, St. Louis, District of Columbia, Pittsburg, Milwaukee, Charleston, and Somerville one each. From erysipelas, Baltimore four, Philadelphia and Cincinnati two each, Brooklyn, New Orleans, and Charleston one each. From cerebro-spinal meningitis, Chicago and Baltimore two each, Philadelphia, Cincinnati, Buffalo, Lowell, and Haverhill one each. From measles, New York three, St. Louis two, Philadelphia, Baltimore, and District of Columbia one each. From small-pox, New Orleans three, Philadelphia two, St. Louis one. From puerperal fever, New York, Chicago, Cincinnati, Buffalo, and Fall River one each.

Six cases of small-pox were reported in St. Louis; scarlet fever 55, typhoid fever 43, and diphtheria 31 in Boston; scarlet fever 17, diphtheria three in Milwaukee.

In 36 cities and towns of Massachusetts, with an estimated population of 1,067,463 (estimated population of the State

1,922,530), the total death-rate for the week was 19.34 against 18.53 and 20.08 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending October 6th, the death-rate was 18.5. Deaths reported 3054: diarrhoea 207, acute diseases of the respiratory organs (London) 191, scarlet fever 114, fever 57, measles 37, whooping-cough 31, diphtheria 26, small-pox (Birmingham six, London three, Sunderland one) 10. The death-rates ranged from 12.3 in Huddersfield to 28.6 in Newcastle-on-Tyne; Bristol 14; Leicester 14.9; Birkenhead 15.9; London 16.5; Sheffield 18.9; Nottingham 19.4; Leeds 19.8; Birmingham 20.5; Liverpool 23.5. In Edinburgh 14.8; Glasgow 18.3; Dublin 23.4.

For the week ending September 29th, in 166 German cities and towns, with an estimated population of 8,598,787, the death-rate was 23.6. Deaths reported 3903; under five years of age, 2037; consumption 480, diarrhoeal diseases 277, lung diseases 255, diphtheria and croup 203, scarlet fever 124, whooping-cough 61, typhoid fever 85, measles and röteln 36, puerperal fever 17. The death-rates ranged from 8.1 in Darmstadt to 37.8 in Königsberg; Breslau 29.5; Munich 26.2; Dresden 24; Berlin 27; Leipzig 25.6; Hamburg 23.3; Cologne 26; Frankfurt a. M. 9.1; Strasburg 19.6.

For the week ending October 6th, in the Swiss towns, there were 26 deaths from diarrhoeal diseases, consumption 20, lung diseases 10, diphtheria and croup three, whooping-cough three, measles one, erysipelas one. The death-rates were, at Geneva 7.1; Zurich 10; Basle 18.3; Berne 16.9.

The meteorological record for the week ending October 20th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps:—

Date.	Barom-eter.	Thermome-ter.			Relative Humidity.				Direction of Wind.			Velocity Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM OCTOBER 19, 1883, TO OCTOBER 26, 1883.

BACHE, DALLAS, major and surgeon. Assigned to duty at Willer's Point, New York. Paragraph 1, S. O. 238, A. G. O., October 18, 1883.

HORTON, S. M., major and surgeon. Leave of absence for one month, with permission to apply for an extension of three months. Paragraph 6, S. O. 216, Department of the Missouri, October 20, 1883.

BARNETT, RICHARDS, captain and assistant surgeon. Assigned to duty at Columbus Barracks, Columbus, Ohio. Paragraph 1, S. O. 240, A. G. O. October 20, 1883.

MAUS, LOUIS M., captain and assistant surgeon. Assigned to duty at Fort A. Lincoln, D. T. Paragraph 4, S. O. 180, Department of Dakota, October 15, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING WEEK ENDING OCTOBER 27, 1883.

VAN REYKEN, W. K., surgeon, detached from the Naval Hospital, New York, and ordered to the U. S. S. Powhatan.

WELLS, H. M., surgeon, detached from the Naval Laboratory, New York, and ordered to the Naval Hospital, New York.

Medical Inspector A. C. GORGAS's orders modified so that he will be detached from the Naval Hospital, Chelsea, Mass., on December 10th instead of November 10th.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, JULY 1, 1883, TO SEPTEMBER 30, 1883.

BAILHACHE, P. H., surgeon. Detailed as member of Board to examine candidates for promotion. August 23, 1883.

Detailed as surgeon in charge, Cape Charles Quarantine Station. September 5, 1883.

MILLER, T. W., surgeon. Granted leave of absence for twenty-five days. August 31, 1883.

WYMAN, WALTER, surgeon. Detailed as member of Board to examine candidates for promotion. August 23, 1883.

LONG, W. H., surgeon. Granted leave of absence for twenty days. September 25, 1883.

SMITH, HENRY, surgeon. Directed to take charge of quarantine service at the Capes. July 29, 1883.

STONER, G. W., passed assistant surgeon. Granted leave of absence for thirty days. August 24, 1883.

To inspect the relief stations along the coast of Maine. September 29, 1883.

GOLDSBOROUGH, C. B., passed assistant surgeon. Granted leave of absence for thirty days. August 29, 1883.

BANKS, C. E., assistant surgeon. Relieved from duty at Portland, Oregon, and to report to the Surgeon-General at Washington. July 10, 1883.

CARMICHAEL, D. A., assistant surgeon. Granted leave of absence for ten days. August 31, 1883.

PECKHAM, C. T., assistant surgeon. To proceed to Portland, Maine, for temporary duty. August 25, 1883.

DEVAM, S. C., assistant surgeon. To proceed to Portland, Oregon, and assume charge of the service. September 11, 1883.

KALLOCH, P. C., assistant surgeon. To proceed to Philadelphia, Penn., for temporary duty. July 25, 1883.

To rejoin his station, New York. July 31, 1883.

YEMANS, H. W., assistant surgeon. Relieved from duty at Sitka, Alaska, and to proceed to Portland, Oregon, for temporary duty. July 10, 1883.

To proceed to San Francisco, Cal., reporting for duty to Surgeon Vansant. September 11, 1883.

GLENNAN, A. H., assistant surgeon. To remain at Norfolk, Va., until further orders. July 29, 1883.

WASDIN, EUGENE, assistant surgeon. To proceed to New Orleans, La., for temporary duty. August 2, 1883.

To proceed to Mobile, Ala., for temporary duty. August 27, 1883.

To rejoin his station (New Orleans) as soon as practicable. September 25, 1883.

PROMOTIONS.

GUITÉAS, JOHN, passed assistant surgeon. Promoted, and appointed passed assistant surgeon by the Secretary of the Treasury from September 1, 1883. August 31, 1883.

WHEELER, W. A., passed assistant surgeon. Promoted, and appointed passed assistant surgeon by the Secretary of the Treasury from September 1, 1883. August 31, 1883.

RESIGNATION.

O'CONNOR, F. J., assistant surgeon. Resignation accepted by the Secretary of the Treasury, to take effect August 1, 1883. August 2, 1883.

APPOINTMENT.

WASDIN, EUGENE, M. D., of South Carolina, having passed the examination required by the regulations, was appointed an assistant surgeon by the Secretary of the Treasury, August 2, 1883.

GYNÆCOLOGICAL SOCIETY OF BOSTON. — The next regular meeting will be held at the Medical Library Rooms, 19 Boylston Place, on the second Thursday of November, at four o'clock P. M. A. P. Weeks, M. D., will read a paper upon Acute Inversion of the Uterus. Lunch served at close of session.

HENRY M. FIELD, M. D., Secretary.

ERRATUM. — In the article in the JOURNAL of October 25th, by Drs. Tilden and Watson, at page 385, in the first nine cases of the second table, recording the cessation of the gleet after operation, read *weeks* instead of *months*.

BOOKS AND PAMPHLETS RECEIVED. — Wood's Library of Standard Medical Authors. A Manual of Practical Hygiene. By Edmund A. Parkes, M. D., F. R. S. Edited by F. S. B. Francois de Chaumont, M. D., F. R. S. Sixth Edition. With an Appendix giving the American Practice in Matters relating to Hygiene, by Frederick N. Owen, Civil and Sanitary Engineer. Vol. I. New York: William Wood & Co. 1883.

Original Articles.

A STRANGE CASE.¹

BY O. T. HOWE, M. D., MEDICAL EXAMINER.

ON the evening of February 28th, a few minutes past nine, I was told that Charles Cate had shot himself in a room over the Pemberton Bank, in Lawrence, Mass. I immediately went there, and on entering the room found Cate lying on his back on the floor. He was still alive, but his pulse was feeble, and his respiration stertorous. I loosened his clothes, moved him into an easier position, and then examined his wounds. Prepossessed with the idea that he had shot himself, I made but a slight examination. I saw what I supposed to be the wounds of entrance and exit, the cuts on the scalp from the pistol butt, and concluded that a post mortem on the next day, for the man was evidently dying, would reveal the exact course of the bullet. The occupant of this room, Mrs. Anderson, was lying on her bed, disabled by injuries presently to be described.

I then turned to examine the room, the plan of which I have here. It was a large room, in the third story of the Pemberton Bank Building, with two windows looking out on Pemberton Street. The door leading into the entry was fitted with ground-glass panels, and had a spring lock. To the right of the door of entrance was a lounge. On the lounge, which was spattered with blood, Cate's overcoat was lying. On the wall above the lounge, about four feet from the floor, was a smear of blood about the size of a man's hand. The ceiling above the lounge was spattered with blood, as was also the door leading into Mr. Osgood's room, a few feet distant. The carpet where Cate was lying was soaked with blood, which flowed freely from his head. To the left of the door as you entered was a large closet. Near the entrance to the closet was a pail half full of dirty water, a pair of shoes and stockings, and a hop-bag. The floor was covered with blood, and blood was spattered over the door, and over a chest of drawers which stood in the closet. The second drawer in this was partly drawn out, and through its side was a bullet hole. In the drawer was found a bullet which fitted the revolver. The other bullet was not discovered at this time. The revolver which had been taken from Cate was an old-fashioned 44 calibre Remington. Two barrels had been discharged, four remained loaded. It was covered with blood, and about the trigger several hairs could be detected. The chamber to the revolver, as I was informed by the officers, had been found lying on the bed.

To the left of the closet was a door leading into Mr. Coan's room. This door was found bolted on Mrs. Anderson's side. There were no marks of blood about the wood-work. Mrs. Anderson had been moved from the closet to the bed. I next examined her wounds. There were one or more severe contused wounds of the scalp, and a bullet wound in the right leg. The ball had entered near the head of the tibia, and passed out about half way down the calf of the leg.

At twenty-seven minutes past nine, or about forty minutes after the shooting, Cate died. I then took possession of his effects. The only things of importance to this paper was a handful of caps in his vest pocket, which fitted the pistol. As I was search-

ing him his nephew, Herbert Cate, told me that I should find a paper sewed in his vest lining which might be of importance. I ripped the vest and took out a sealed envelope, the contents of which proved to be some twenty grains of sulphate of morphia. The body was then given up to the undertaker. A closer examination of the closet the next morning disclosed the other bullet and an indentation in the wall where it had struck. On the ball were some fragments of woolen corresponding with Mrs. Anderson's skirt.

The autopsy was held the next day, seventeen and a half hours after death, Drs. Sargent, Dow, and Abbott assisting. The following is a condensed account of it:—

Rigor mortis well marked. The body was that of a strongly built, well developed man, about five feet nine inches in height, weighing about 165 pounds. The face was pale; eyes closed; pupils slightly dilated. The hair was matted with blood. On the right cheek, a little below and to the right of the eye, were two or three small ecchymoses. Above and to the right of the right eyebrow there was a shallow cut about half an inch long. On the right temple were two cuts about the same size and depth, and a triangular cut an inch long on one arm, and half an inch on the other. Two inches above the right ear was a lacerated wound about two inches long by one broad, laying bare the skull. On the vertex were nine distinct cuts, each about three fourths of an inch long, slightly convex towards the face. These cuts were all separated from each other, covering a space of two and three fourths inches in length by two in breadth. Directly back of these cuts the skull was exposed for a space of three inches in length by two in breadth, the edges of the wound being much lacerated.

On removing the skull-cap the dura mater was rather easily detached; the pia mater reddened and injected. The vessels on the surface of the brain were full of dark fluid blood. On removing the brain nearly a pint of dark fluid blood and serum escaped from the severed vessels. There was no fracture of the skull, and no extravasation of blood on the surface of the brain or into its substance. The brain was large and apparently healthy. Cut sections were made without noting anything abnormal.

Examination of the Thorax. The pericardium contained half an ounce of serous fluid. The right ventricle of the heart contained nearly a fluid drachm of dark, partly fluid, blood. The left ventricle contained somewhat less. The structure of the heart was healthy; its valves were normal. The left lung was somewhat darker than the right, and contained more blood. Both lungs were normal in consistency.

The stomach contained over a pint of gruel-like fluid, yellow in color, and consisting of partly digested food, which gave off a somewhat sour smell. The mucous membrane was slightly injected. No evidence of disease or poisoning was observed.

All the other organs of the body were examined, and nothing sufficiently abnormal to have had any effect on the case was found. The anus was closed, and there was no sign of fecal matter about it.

The opinion of the medical examiner and of the physicians present was that the man died from self-inflicted wounds, the direct cause of death being shock or concussion.

The only question I had to decide as medical examiner was the possibility or impossibility of the wounds being suicidal. Taken *per se* it was, of course, more

¹ Read before the Massachusetts Medico Legal Society at the annual meeting, June 12, 1883.

probable that they were homicidal, but the evidence was very strong against it. I will now proceed to consider the evidence on which the above opinion was founded, and I will begin with Mrs. Anderson's testimony, given as soon as she recovered sufficiently to speak:—

"On the evening of February 28th I left my store at about seven o'clock with a sick headache, to which I am subject. I went directly to my room, and got a bucket of water, and made a hop-bag. I was soaking my feet, with the hop-bag on my head, when some one rapped at the door. I said, 'Is that you, Will?' (meaning my brother); Cate then spoke, and I knew his voice. I told him to go away, but he forced the door open, and said, 'Why did n't you open the door?' I said, 'I don't want you here; go away.' Then he pulled the hop-bag off my head, and struck me with something, I don't know what. I screamed, and ran into the closet, and he fired at me twice. I pulled the door to, and then I heard what I thought was the click of the pistol once or twice; then in a moment or two I looked out, and saw Cate pounding himself on the head with the pistol. Then I suppose I fainted."

This was Mrs. Anderson's testimony, which I am inclined to believe was the truth, but not the whole truth. Before showing how far it was corroborated it will be necessary to introduce the other witnesses.

As I have already stated, a door opened from Mrs. Anderson's room into Mr. Osgood's. In his room that evening were Mr. and Mrs. Osgood, and a Mr. Fisk. On the other side was Mr. Coan's room, but this was unoccupied between the hours of seven and twenty minutes past nine. Both of these doors had shrunk, allowing sounds to pass through readily. On the floor above Mrs. Anderson's room there were a number of persons present that evening, Helen Claystone and her mother, Letty Savage, Mr. Worswick, Mr. Robinson, and some others. The other witnesses were the officers and parties on the street.

Mr. and Mrs. Osgood and Mr. Fisk gave testimony to this effect:—

About fifteen minutes after seven they heard Mrs. Anderson go into her room, and light her lamp. In a short time she came out, and went into the kitchen, which opens out of their room, and is used by all on the floor; she drew a bucket of water, and went back to her room. They heard nothing more until the rap on the door. They would naturally have heard any talking or unusual noise in Mrs. Anderson's room. About half-past eight Mr. Osgood came out of his room, and went up stairs. He then saw Cate standing in front of Mrs. Anderson's door. He stayed up stairs a few moments, and when he returned Cate was still there. He went into his room, and immediately after a rap was heard on Mrs. Anderson's door. A woman's voice replied, and then the door was forced open. Voices were heard for a moment, then a blow and scream, then two pistol shots. Mrs. Osgood threw up the window, and called "Police!" Then sounds were heard which seemed like clicks or blows (the evidence as to this varied), then louder sounds like blows, then all was silent.

In a time long enough to run down a flight of stairs, Mr. Robinson appeared on the scene. He was immediately followed by Miss Claystone and Mr. Worswick. Mr. Robinson tried the door, it was locked; through the ground glass of the panel he saw a shadow cross the room towards the lounge, and the light went out. This was also witnessed by Mr. Colcord, who was just coming

up the stairs, and by Miss Claystone in the entry. To Mr. Colcord it seemed as if the shadow was waving its hands. Mr. Worswick then ran down stairs for the officers, and the other three remained, watching the door. Within a time, variously estimated from two to ten minutes, but which careful sifting of the evidence brings down to not more than three or four minutes, three officers and Messrs. Trickey and Sweeny appeared on the scene. The officers burst open the door, and Cate was seen sitting on the lounge, with the revolver in his hand. As they entered Cate rose up, and was disarmed by the officers. He then fell back insensible. While this was taking place Mr. Sweeny stood in the doorway so that no one could pass out; the room was dimly lighted from the hall and street lights. A lamp was soon brought, and a careful examination of the room made. Cate, his head and hands covered with blood, was laid on the floor. Mrs. Anderson was lifted from the closet floor where she was sitting, and placed upon the bed. No third party, or any trace of a third party, was found in the room. The door leading into Coan's room was found bolted on Mrs. Anderson's side, Mrs. Osgood's door was also found locked. Mrs. Anderson then gave her testimony to the officers. The two bullets were both found, confirming her story that both shots were fired at her. The wounds on her head and on his might both have been given by blows from a revolver such as Cate held in his hand. The bucket of water, the shoes and stockings, the hop-bag; these were all silent witnesses to the truth of her story. The sound of blows, the click of the pistol as it missed fire, these were all confirmed by other parties.

From the time of the pistol shot, then, the door leading into the entry was watched; no one went out; three or four minutes passed and the officers broke in; no one went out, the room was searched, no third party was there. If any other person was concerned in the tragedy, he must have clubbed Cate fourteen or fifteen times after Cate had shot the woman; and these blows must have been given apparently without resistance on the part of Cate, who was a strong, powerful man, armed with a revolver. In some mysterious way, after the assault, the assassin had vanished.

Mrs. Anderson's room was in the third story, with the windows looking out on Pemberton Street. Mrs. Carlisle, who roomed across the street, at the sound of the pistol shot went to her window and remained watching Mrs. Anderson's room until the lights were brought. It was impossible for any one to have escaped that way. A door opened into Mrs. Osgood's room. But in the room were three parties, and between the door and doorpost paper had been packed to dull the sound; this was undisturbed.

A door opened into Mr. Coan's room, but he could swear that on that evening he left the door locked on his side with the key in the lock, and found it so on his return. The door leading from his room into the entry was also locked, and the key in his pocket. The officers also testified that the door was found bolted on Mrs. Anderson's side. It was of course impossible that any one could have let himself out through this door and then locked it on both sides. Mr. Robinson was the first person on the scene, and he had a key to the room; but we have the testimony of Miss Claystone and Mr. Worswick, that Mr. Robinson ran down the stairs just in front of them, and that certain of the occurrences in the room took place while they were all three watching.

So with any other party; the time was so short, and so many witnesses were around the door, that it would seem impossible for any one to have given Cate the injury and then escaped. The only way a person could have left the room by any human means was through Coan's room; and here the evidence, as I have stated, was very clear.

Mrs. Anderson's testimony, then, seems to be corroborated by both direct and circumstantial evidence. It would certainly be unnatural for a woman to entertain a gentleman in her room while engaged in washing her feet, as she evidently was. It would be impossible that she should invent a story as soon as she recovered from her faint which would bear the test of investigation, she at the time not being sure but what Cate might survive.

There is one point, however, where her story, to say the least, was incomplete; the night of the tragedy there was a masquerade ball in a hall not far from her room. As afterwards appeared, she had promised a young gentleman to go and dress him for the ball that evening. She did go, and, as he testifies, was in his room from a quarter before eight to a quarter past eight. This she does not allude to in her evidence. She must have gone to her room about fifteen minutes past seven, stayed there for half an hour or so, and then gone over to the hall, and returned about twenty minutes after eight. This circumstance, however, serves to give a possibly immediate motive for the attempted murder.

Cate was very jealous of Mrs. Anderson. That evening he was seen by Mr. Robinson between seven and eight o'clock to enter the Pemberton Bank Building and go up stairs. In about five minutes he came down and went away. It is very possible that he watched her, and saw that she went to the masquerade, and that this was the spark that lighted the conflagration. I would say here, that there was not the slightest reason to suspect Mrs. Anderson and the young man of any intrigue, and it was easily proved that at the time of the shooting he was in Saunders' Hall. Once before Cate had quarreled with Mrs. Anderson, and he had been put under bonds to keep the peace. At that time he had taken this same Remington revolver to Mr. Frost, a gunsmith, and had it put in repair. It was identified by Mr. Frost at the inquest.

Cate's friends for some time had had doubts of his sanity. A week before the tragedy his nephew, Herbert Cate, warned him to keep away from Mrs. Anderson, or he would again be arrested. "Don't you fret," was his answer, "I shall never be taken alive;" and then he pointed out to him the package sewed in his vest, but without explaining what it was.

He was, then, a desperate, very probably insane man, wild at Mrs. Anderson's evident desire to get rid of him. I believe that, jealous on account of her visit to the masquerade, he returned to his room, got his pistol, and came back intending to kill Mrs. Anderson and then to commit suicide.

The whole story of the crime seems to point to insanity. He struck her over the head with a loaded pistol. He fired at her twice and missed with one barrel, although the weapon was used not more than three or four feet away. My theory is that he then tried to shoot himself, and that for some reason the pistol did not go off; that he then took out the chamber to see what the trouble was, and, hearing the door tried, in his confusion threw the chamber on the bed, walked across to the other side of the room, blew out the light,

and then began striking himself on the head. The morphia in his vest he evidently meant as a last resort, should he be taken to the station house.

There are several circumstances connected with this case of a very mysterious nature. For example, why did not Cate shoot himself instead of pounding himself on the head? Why was the chamber out of the revolver? Why was the light out? Why did not Mrs. Anderson tell of going to the masquerade? These points I have indicated and tried to answer. Mr. Frost, the gunsmith, tested the revolver and had no difficulty in firing it; he also testified that the chamber must have been taken out and could not have fallen out; it was possible, he said, however, that it might have been jammed and had not revolved that night.

I now come to the more strictly medico-legal points of the paper:—

(1.) Did Cate die of the wounds received on the head, or were they only factors in a result due also to poison or existing disease? A thorough examination was made of the body, and no indication of disease or poison was found. That he had taken no irritant or specific irritant poison was evident. There was no pin-hole contraction of the pupil, no vomiting, no diarrhoea, no convulsions. No bottle or paper containing poison, or likely to have contained poison, was found on or about his person, except the package of morphia which was sewed in his vest. I believe he died of the wounds received, and of them alone.

(2.) What was the immediate cause of death? The autopsy revealed no extensive extravasation of blood on the surface or into the substance of the brain; there was no fracture of the skull; beyond congestion of the vessels of the brain there was almost nothing to show cause of death.

Taylor says:¹ "Wounds of the head are dangerous in proportion as they affect the brain, and it is rare that a severe contused wound is unaccompanied by some injury to this organism. It is important to remember that neither compression nor physical injury to the brain is necessary to render concussion fatal; after death no particular morbid change may be discovered in the body." And again:² "Death may take place from the disturbance of the function of any organ important to life without this being necessarily accompanied by a perceptible alteration of structure." The history of the case and the result of the autopsy establish to my satisfaction the fact that Cate died of shock or concussion. No one of the wounds apparently was severe enough to have caused immediate insensibility, yet taken together they produced the effect of one crushing blow. "It is a well-known medical fact," here I quote again from Taylor, "that a number of injuries, each comparatively slight, are as capable of operating fatally as any single wound."

(3.) Could a man who had received fatal injuries on the head, of the character described, possess the power of locomotion, or would they necessarily be accompanied by immediate insensibility? Taylor says³ that a man after a severe compound fracture of the skull may nevertheless be able to walk for some distance and then fall dead; that severe injury to the head or great effusion of blood is not necessarily accompanied by immediate insensibility or loss of motion. So, also, Woodman and Tidy, in their work on Fo-

¹ Medical Jurisprudence, page 341.

² Ibid., page 316.

³ Ibid., page 347.

rensic Medicine, state that the symptoms of shock are usually immediate, but there may be an interval between the accident and the symptoms. In this case we may perhaps assume that the lighter blows were first delivered, and that only as the officers came up stairs and the increasing probability that he would be taken alive was forced upon him did he deliver the heavier and more fatal blows.

I think, then, we may say that while it would be more natural to expect immediate insensibility, it is not impossible that the power of locomotion may remain for a brief period, and yet the patient die of shock.

(4.) Could the wounds on the head have been self-inflicted? The announcement of the result of the autopsy, that Cate had committed suicide, was received with considerable incredulity not only by the laity but also by some of the profession. Leaving out the evidence, however, there were some things in the character of the injuries themselves that looked like suicide. That the wounds were all either on, or to the right of, the median line, looks as if they were given chiefly with the right hand of the person himself. The nine convex cuts, all crowded into a comparatively small place, show that the head must have been kept quiet while the blows were delivered. In any personal conflict it would be almost impossible that nine wounds should be received in a space of two square inches unless we assume that the receiver was insensible. Moreover, these wounds were all shallow, evidently given with feeble force, characteristic of suicidal rather than homicidal violence. "Contused wounds," says Taylor, "are rarely seen in cases of suicide, but there are exceptions to this remark. When persons laboring under insanity commit suicide they often inflict upon themselves wounds of an extraordinary kind, such as would at first view lead to the suspicion that they had been produced by the hand of a murderer. In one instance which is reported, a lunatic in committing suicide inflicted thirty wounds on the head." I think we can say, then, that it was perfectly possible that the wounds were self-inflicted, and yet in the death and in the whole story there remains sufficient mystery to make it what I have styled my paper, *A Strange Case*.

A CASE OF TWO-HORNED UTERUS (UTERUS BICORNIS),

THE LEFT HORN NOT COMMUNICATING WITH THE VAGINA AND DISTENDED BY MENSTRUAL BLOOD, FORMING A LARGE TUMOR. SUPRA-VAGINAL REMOVAL OF UTERUS, OVARIES, AND FALLOPIAN TUBES. CURE.¹

BY JOHN HOMANS, M. D., BOSTON,
Surgeon to the Massachusetts General Hospital.

Miss L. S., a farmer's daughter in Vermont, eighteen years old, was sent to me in April, 1883, by Dr. Ellis, of Poultney, Vt. She was a healthy girl, but had a worn look as if she had suffered much from pain. The girth at the umbilical level was thirty and a half inches, and there was a globular tumor with thick walls filling the lower middle part of the abdomen and pelvis. The tumor was movable, it had no adhesions; fluctuation and impulse were both distinct. Tenderness of the abdomen was universal. The dullness extended an inch above the umbilicus. On auscultation no sounds were transmitted through the tumor. The right lumbar re-

gion was resonant, the left was dull. The uterus could not be found. The vagina was filled with a tightly distended elastic tumor which pushed the rectum forcibly backwards. Menstruation had begun at fourteen years of age. It had been irregular and deficient. Her appetite was poor and also her sleep. Her pulse was 100. She had dull pain in the pubic region, and suffered almost constantly from pain and tenderness. Formerly her left leg was swollen, but is now normal in size. One year ago she noticed that she was increasing in size, and the tumor has risen up and spread out. She thinks that there has been some periodical increase and diminution in the tumor. This somewhat detached account of the case does not make sufficiently prominent the principal factor, and the one that induced me to operate, namely, the agonizing pain. The patient said she was willing to die of any operation that promised the least hope of amelioration. On April 11, 1883, I operated at the Carney Hospital. I made an incision from the umbilicus to the pubes, and on cutting through the parietes the marks of an old hæmorrhage (hæmatocele) were met with in the cellular tissue of the pubic region. On getting through this confusing mass of old blood clot and muscular tissue the peritonæum was opened. The tumor was found to have an adhesion to the omentum and to be semiglobular in shape, and to be incorporated with the floor of the pelvis, the rectum, and the bladder, and, in short, to be the uterus filled with fluid and distended to about the size of a small foot-ball or a large cocoanut. The right ovary and Fallopian tube were tied and burnt off. The left ovary was tied, and it was found that a mass of irregular sausage-shape was connected with the left broad ligament and Fallopian tube. This mass puzzled me at first, and I could not tell whether it was intestine or tube, or a mass of hæmatocele, or an old aneurism. The anterior and lower pelvic region were more or less filled with shreddy remains of old hæmatoceles. The globular swelling was now punctured, and the cavity of the uterus emptied. Its wall, at the seat of puncture, was an inch or more in thickness. Several pounds of dark fluid blood without clots ran out and welled out. The cut surfaces of the uterus bled pretty freely and were clamped. The uterus immediately began to contract in size, and was much smaller at the close of the operation than when the abdomen was opened. It seemed impossible to remove the whole uterus, as its lower pelvic portions could not be raised. A wire was passed around the uterus just above the bladder and as low as possible, but it broke. One of Mr. Wells' large ovariectomy clamps was then put on, and a large portion of the uterus and the left Fallopian tube and ovary were removed. An elastic catheter was passed into the cavity of the uterus (between the jaws of the clamp). The operation was done under the carbolic spray, and the wound was dressed antiseptically. It seemed at first as if the os uteri might have been found and the uterus drained through it, but the cavity I opened did not communicate with the vagina, and from the state of the pelvic organs it seemed to me that menstruation would go on, and perhaps the same state of things would be reestablished as existed before the operation, or even a more serious one, for it would have been difficult to have kept the artificial cervix open, and there was a large wound in the roof of the uterus through which blood was constantly oozing; consequently I decided to remove all of the

¹ Read before the Boston Society for Medical Improvement, October 22, 1883.

uterus that I could clamp, and also both ovaries and tubes, so that menstruation would be done away with. The patient suffered from considerable pain for two days, and thirty-six hours after the operation had a smart hæmorrhage. I was called at one A. M., and found the clamp loose, the uterine tissue having shrunk away from it. I tied beneath the clamp with carbolized silk, but the hæmorrhage had already ceased. Twelve hours later another slighter hæmorrhage took place. No more hæmorrhage occurred after this, but much black fluid blood was discharged upon the dressings and syringed out. The wound was syringed once or twice a day, under the spray, as was necessary, and the tube was gradually shortened. The temperature during recovery varied from 98° F. to 101.4° F. on the second day, but averaged very nearly normal, and the pulse was never over 100.

She left the hospital on the thirtieth day after the operation, and soon afterwards returned to the country, having gained flesh and strength and color in her cheeks, and being wholly free from pain. There was a small granulating surface at the site of the wound which was depressed and looked like a second navel which had been pulled inwards. The os uteri could be felt in the upper part of the right side of the vagina, but a sound was not inquisitively pushed through it, as I preferred to let well enough alone for the present. I hope to see the patient at some future time, and shall perhaps be bolder in my investigations. The specimen was handed to Dr. A. N. Blodgett, and the following is his account of it:—

The specimen consists of the fundus and body of the uterus, which has been amputated at the cervix. Attached is the left broad ligament, the left Fallopian tube, the left ovary, and a sac, the size of a large orange, situated at the pelvic extremity of the broad ligament. The right ovary is present, but is detached from the other organs. The right Fallopian tube and broad ligament are not apparent. Upon the peritoneal surfaces of the uterus and the entire surfaces of the broad ligament are adherent remains of partially organized blood coagula, which hang as shreddy tufts from every part of the serous surface. Upon the posterior aspect of the broad ligament is a sac, the walls of which are composed of dense shreddy coagulum, but which has no present contents.

The uterus is deformed, the left horn being greatly distended, forming an oblong conical pocket which is impervious at its superior extremity, there being complete atresia of the left Fallopian tube. The right horn of the uterus is apparently normal in size and relatively very short. The section by which the amputation of the organ was effected passed through the body of the uterus at a point in which the left Fallopian tube still constitutes a separate cavity in the wall and body of the uterus, thus presenting two openings upon the amputated surface, one the cavity of the uterus proper, or perhaps better described as that of the right horn of the uterus, and the other the canal of the left Fallopian tube and left horn of the uterus. The wall of the uterus is very thick and dense; on the right side it is much thinner, and the thickness constantly diminishes toward the region of the Fallopian orifice. The tissues are at present everywhere wrinkled and contracted, but the uterus is said to have been the size of a child's head at the time of the operation.

The present appearances are as follows: From the seat of amputation to the top of the right cavity in the

middle line five centimetres. From the same point to the extreme end of the cavity in the left horn eleven centimetres. Thickness antero-posteriorly through both walls 4.5 centimetres. From side to side six centimetres. The lining of the right uterine cavity is apparently normal in every respect, and is everywhere thrown into numerous minute folds. The lining of the left cavity differs from that of the right only in respect to the more natural arrangement and condition of the glandular structures of the mucous membrane, which are very striking in this particular specimen. Both canals are everywhere surrounded by normal uterine muscular tissue.

The ovaries are of nearly equal size, and measure each 4.5 centimetres in length by two centimetres in breadth, and 1.5 centimetres in thickness. Their surfaces are covered by shreds of coagulum, and they are softened and elongated. Upon section of the right ovary a corpus luteum is found in the stage of grayish yellow absorption, the cavity being linear and almost entirely obliterated. The contents was a mass of finely granular fatty detritus. No other corpora lutea were here observed.

In the left ovary a number of firm, rounded bodies were felt, some of which bulge slightly above the surface and have the size of a pea. There are also small superficial depressions of some parts of the surface covering the ovary. These being incised led to sacs the size of a pea, containing a bloody fluid. The lining membrane of these small sacs was covered with columnar epithelium, the cells of which are often in a state of more or less advanced fatty degeneration. The interstitial tissue of the ovary consists of a loose, long, spindle-celled connective-tissue structure, soft in feeling and easily separated. In the left ovary no corpora lutea were observed.

The left Fallopian tube was found and its canal followed as far as the junction of the tube with the body of the uterus, where there is complete atresia of its lumen. Its canal is pervious for a distance of eleven centimetres from the body of the uterus to its point of attachment to the before-mentioned sac contained in the broad ligament, at which situation the Fallopian tube is lost. Nothing like a fimbriated extremity can be found. The mucous membrane lining the tube is atrophied, and no ciliated epithelium can be anywhere discovered. The sac in the broad ligament is a cavity consisting of a membrana propria quite thick and elastic, which is at present thrown into loose folds, and an outer layer of peritonæum covered with fringes of organized blood coagula-like adhesions. The lining of the sac was everywhere covered with a layer of pasty matter of a dull red color, which proved to be grumous blood. Upon the posterior wall of the sac were found two distinct perforations in the lining membrane which extended through the entire thickness of the membrana propria and peritonæum, and communicated by free orifices with the abdominal cavity. Other small perforations of the lining of the sac led down to deposits of grumous blood in the tissues, varying in size from that of a shot to that of a Lima bean. Upon the peritoneal surface of the broad ligament near the perforations is a large mass of blood coagulum, a portion of the hæmatocele below alluded to. No connection between the sac in the broad ligament and the ovary is apparent, and no afferent blood-vessel can be discerned.

The pathological condition, so far as this can be determined from the specimen, is the following: There

is essentially a double uterus, the two Fallopian tubes being prolonged toward the cervix so that in amputating the body of the organ two distinct canals are found. The orifice of the right tube communicated with the vagina, while there was complete atresia of the lower extremity of the left canal. The secretions of this cavity had gradually accumulated so as to cause a great distention of this portion of the uterine body. There is a distinct sacculated cavity within the outer portion of the broad ligament which at present contains a considerable amount of grumous blood, and which communicates by two separate and independent openings with the peritoneal cavity, and which had evidently given rise to the large amount of shreddy coagulum at the seat of the peritoneal openings upon the broad ligament, and formed the source of the blood found in the pelvis as an old hæmatocele at the time of the operation. Several other openings of the membrana propria of the sac led to small isolated hæmorrhagic deposits in the tissues beneath, after the manner of a dissecting aneurism. In some of these small sacs the blood has the consistency of putty, in others the absorption of the blood has progressed to such an extent as to leave only a small deposit of coloring matter in the part. At the seat of the perforations above mentioned the interior of the large sac is lined with a firm reddish-brown layer, similar to that seen in the cavity of a true aneurism when healing by obliteration.

THE TREATMENT OF PSORIASIS.¹

BY ARTHUR VAN HARLINGEN, M. D.

PSORIASIS is one of the commoner skin diseases met with in this country. The statistics of the American Dermatological Association show that it occurs in the proportion of about six per cent. in all diseases of the skin encountered. Daily experience would seem to indicate a still more frequent occurrence, because the affection is a disfiguring and annoying one, and therefore patients are more inclined to seek relief, and also because it is a stubborn disease and greatly prone to relapse. The history of a single case will often extend over many years, and bring it under the observation of a number of different physicians.

It is because of the comparative frequency with which psoriasis is met and its stubbornness to treatment, that I have selected it as the subject of my remarks this evening. Having had a good deal of experience in the treatment of the commoner forms of the disease, it is my intention to confine myself chiefly to the consideration of such remedies as have come under my own observation and use, only touching incidentally on others.

The object of treatment in psoriasis is the removal of the eruption as it exists upon the skin. We cannot hope with any degree of certainty in any given case to prevent a recurrence of the disease, or, if you please, a relapse. For the drug has not yet been discovered which will surely take away all tendency to the recurrence of psoriasis, and whoever promises a cure, in the wider sense of the word, to his patient, will, in a very great number of cases, find that he has been too sanguine. Fortunately, however, a certain number of patients do seem to recover. I do not know what has

been the experience of others in this respect, but I have patients who have been under observation three, five, even eight and ten years without relapse. Such cases are, unfortunately, few.

Preëminent among the internal remedies which are useful in the treatment of psoriasis is arsenic, which may be justly called a specific in this disease. I think I am not asserting too much when I say that eight out of ten cases of psoriasis of average character and severity will do better under the use of arsenic than with any other remedy. I prefer Fowler's solution given in the average dose of four minims thrice daily. I think this solution is often prescribed in too large doses, and I am sure the dose of five to ten minims, as given in the books, is too large for ordinary use. Most patients bear a four-minim dose very well, but there are idiosyncrasies. I have sometimes been obliged to limit the dose at the beginning to one minim in cases where subsequently such toleration has been established that twelve minims have been taken with impunity. However, four minims is a good dose to begin with, and if the effect does not begin to show itself within ten days or two weeks, the amount may be gradually increased. Fowler's solution should never be given to the patient in a vial with directions to drop out the requisite number of drops. The patient is apt to make a mistake, vials of different sizes may pour out more or less in each drop, and there is always danger in leaving a half-empty vial of poison about the house. The solution is better given mixed with water, or with wine of iron or other convenient vehicle.

The effect produced by arsenic upon the eruption of psoriasis is, first, in diminishing the quantity of epidermic scales thrown off, and then in preventing the appearance of new lesions. The patches gradually lose their scalliness, begin to heal in the middle, and disappear little by little. It must be remembered, however, that arsenic is a slowly acting remedy, and its use should be continued through many months to get the best security against relapse.

The other liquid preparations of arsenic used in psoriasis are Pearson's solution of the arseniate of sodium, and Donovan's solution of the iodide of mercury and arsenic. I have used the former in a few cases without noticing any perceptible difference as regards efficiency between it and Fowler's solution. The solution of mercury and arsenic (Donovan's) I have employed in certain stubborn cases with good effect where Fowler's solution has seemed to fail. The existence of syphilis as the cause of the eruption in these cases having been excluded, I am at a loss to account for the apparently greater efficacy of the mixed treatment. The dose given was as much as ten drops, and although this solution is weaker in arsenic than Fowler's, yet I am inclined to the opinion that the conjoint administration of the two drugs, mercury and arsenic, was the cause of the good result rather than the increased dose. I should be inclined to use Donovan's solution in cases where Fowler's solution shall have failed.

The mixture of arsenious acid, black pepper, and sugar of milk, known as Asiatic powder, and recently placed in the Pharmacopœia with the pepper left out, among the triturations, is of no particular value above the other preparations, and is not so convenient of administration.

Hypodermic injections of solutions of arsenic have been employed in the treatment of psoriasis, but I have had no experience in their use.

¹ Read before the Philadelphia County Medical Society, October 17, 1883.

Next in value to arsenic in the treatment of psoriasis is iron. I commonly employ the tincture of iron in cases where arsenic does not seem indicated. There is one type of psoriasis which includes robust, rosy, well-nourished individuals, "the very picture of health." Such people have never been sick a day in their lives, or perhaps may have had slight attacks of articular rheumatism. Such patients do well under arsenic.

But there is another type in which the individual is thin, poorly nourished, and perhaps somewhat anæmic. These are the cases which do well under iron, which is best administered in the form of the tincture of the chloride. With these two remedies, arsenic and iron, I usually succeed in curing ordinary cases of psoriasis, adding in rare cases cod-liver oil to the use of the tincture of iron when debility is present. Of course local applications are employed at the same time. Of these I shall speak presently.

In addition to the internal remedies mentioned, quite a host of others have been employed from time to time. Such are tar, carbolic acid, copaiba, phosphorus, tincture of cantharides, tincture of maize, carbonate of ammonia, acetate of potassium, and other diuretics; the alkalies, as liquor potassa, and the alkaline mineral waters. Of these I have found alkalies and diuretics useful in cases when a markedly inflammatory condition of the skin has existed. The other remedies I have not employed, nor do I think the reports of their usefulness based on a sufficient number of facts, except in the case of tar possibly, to make it worth while to try them.

Equally important with the internal treatment of psoriasis is the external management of the disease. It is, of course, desirable to remove the eruption as soon as possible wherever it may be situated; but when it is found upon the face, there is every reason to endeavor its cure by all means and in the shortest time. External and internal treatment should therefore be combined when practicable. The first thing to do is to remove the scales. This may be done by means of local or general baths, wet dressings, etc., or by inunctions with fats and oils, by the use of soap, or by the action of impermeable dressings of India-rubber or oil silk. When only a few lesions are to be acted upon, a solution of salicylic acid in alcohol, one part to sixteen, well rubbed in with a sponge, will remove the scales very nicely.

The scales having been removed, the next thing is to apply such substances to the diseased patches as may most quickly modify the abnormal condition of the skin, and bring it back again to a healthy condition.

An innumerable number of applications have been recommended for this purpose, the most of which I shall pass over with only a mention. Such have been soaps and alkalies, citric and hydrochloric acids, sulphur, iodine, and mercury, alone and in combination, together with the various forms and preparations of tar, creosote, and carbolic acid.

All of these remedies have their uses, and most of them, especially the tarry preparations, I have employed time and again in years gone by and with moderate satisfaction. The introduction, however, of chrysarobin or chrysophanic acid some six or seven years ago put quite a new face on the local treatment of psoriasis; and since then, with the aid of this and other later discoveries, we are able to work a much more rapid change in the appearance and condition of the skin in this disease.

As chrysarobin is perfectly well known to all here present, both as to its advantages and defects, I shall say but little about it in the ordinary form of its application, namely, as an ointment. When it first came out I tried it quite extensively, but its disadvantages seemed so great that I had already begun to restrict its use greatly in my practice, when a new agent appeared, which for every-day use has in my hands, until very recently, almost entirely superseded all other local applications. I refer to pyrogallallic acid.

I do not think pyrogallallic acid is by any means so well known as an application for the relief of psoriasis as is chrysarobin. If I may judge by the infrequency with which its virtues are mentioned in the journals (although I believe all recent text-books speak of it), it is not in general use. But it is, in my opinion, one of the very best remedies we have for the cure of cases of psoriasis of average severity. Employed in the form of ointment, of the strength of one half to one drachm of the pyrogallallic acid to one ounce of simple ointment, the effect produced by it is almost as rapid and decided as that brought about by chrysarobin, without the accompanying discoloration. A slight, blackish staining is all that is produced, and the ointment can even be employed in the scalp without markedly discolorizing the hair, if applied cautiously. It is desirable, however, not to apply soap or alkalies at the same time, because this causes a more permanent and deeper stain.

Pyrogallallic acid cannot be used in extensively generalized psoriasis, when large surfaces are affected by the disease, without a certain amount of danger from absorption, as indicated by strangury and olive-green or tar-colored urinary secretions. With care, however, and the occasional suspension of the remedy for short periods, I believe this remedy could be employed even in universal psoriasis with good effect.

One more external application in psoriasis remains to be spoken of, namely, naphthol. This drug, a derivative of coal-tar, was introduced into use several years ago by Kaposi, of Vienna, as a sort of substitute for carbolic acid. He recommends it very highly in psoriasis, in the form of ointment, about eighty grains to the ounce, and I have used it in this and other strengths, and also in solutions in alcohol and oil, with fairly good effect.¹

Naphthol is not so active in its effect as chrysarobin or pyrogallallic acid, but it is much more agreeable, and is, I think, peculiarly well adapted for employment upon such parts as are exposed to the view, as the face and hands. Like pyrogallallic acid, it must be used with caution over large surfaces, as absorption with toxic effects may be produced.

It remains to mention briefly two or three methods of application of these remedies which have recently been brought forward. The first of these is the treatment by medicated gelatine which was introduced by Professor Pick, the well-known dermatologist of Prague. My attention was first drawn to this by a pamphlet which Professor Pick kindly sent me, in which he gave an account of his earlier experiments with medicated gelatines, but I have not as yet had an opportunity of testing this method of medication as I

¹ In a communication read before the American Dermatological Association last month, and published in the American Journal of the Medical Sciences for October, I have given the results of my experience in the use of naphthol in various diseases of the skin, psoriasis among the number. I may refer to that paper for further details as to the action of the drug in this disease.

should desire. I may say, however, that the method does not seem to me calculated to prove convenient and popular in private practice. I had for some time been making some experiments in my service at the Polyclinic in the preparation of gelatines impregnated with chrysarobin and pyrogallie acid, but without much satisfaction, when Dr. Charles L. Mitchell, the well-known pharmacist of this city, sent me some excellent preparations of his own, which seem to be perfectly adapted to the purpose for which they are intended. A bit of one of these gelatine sticks is cut off and placed in a water-bath, where it soon melts into a clear homogeneous fluid, which may then be applied to the lesions of the skin by means of a paint-brush. The advantages claimed are cleanliness and transparency. The coating of gelatine does not rub off on the clothes, and is therefore not so dirty as an unctuous application. A fresh coating can be painted on every day or two as the old layer wears off. The chief disadvantage of this method of treatment is that it requires apparatus which is not convenient to carry about, nor can the patient be trusted to employ it at his discretion. My own experience is that in psoriasis, at least, the gelatine applications are not active enough. I have not, however, used them with sufficient frequency to pronounce a positive opinion.

Recently a solution of chrysarobin in collodion has been recommended in the treatment of psoriasis by Dr. George H. Fox, of New York, and several dermatologists have confirmed his statements with regard to its efficacy. I have employed this preparation in one or two instances, but it has seemed to me so much less active than the chrysarobin ointment that I have not been encouraged to continue its use. It has one great advantage over the gelatine applications, however, and that is that it can be applied extemporaneously and without the paraphernalia which must accompany the use of the gelatine.

A few weeks since a pamphlet by Professor Auspitz, of Vienna, reached me, in which that distinguished dermatologist recommended liquor gutta-perchæ as a vehicle for the application of chrysarobin. I at once obtained a ten per cent. solution, or rather emulsion, of chrysarobin in liquor gutta-perchæ, and happening to have a case of psoriasis of the face and scalp under treatment, I gave some to the patient to apply once daily. The effect was so happy as to encourage me very much to hope that we have in this preparation the most convenient method of applying chrysarobin yet devised; and as chrysarobin is, after all, the most efficient local agent in the treatment of psoriasis as yet brought forward, I have no hesitation in urging the trial of this preparation on any one who may have a case of psoriasis under treatment. It is to be noted, however, that the same watch must be kept upon the skin for fear of exciting dermatitis as when the ointment is used. Only when the liquor gutta-perchæ dries, which it does very quickly, there is little or no danger of rubbing the chrysarobin over the good skin, nor is there much danger, if any, of staining the clothing.

— Dr. Tanner, the notorious faster, has been arrested at Jamestown, N. Y., for practicing on a diploma from a so-called Eclectic College, which has no legal recognition. As usual in such cases he claims it to be a case of persecution aimed against eclecticism.

NAPHTHOL. ITS MEDICINAL USES AND VALUE.¹

BY JOHN V. SHOEMAKER, A. M., M. D.,

Physician to the Philadelphia Hospital for Skin Diseases, Lecturer and Instructor on Diseases of the Skin in the Summer School and Post-Graduate Course of Jefferson Medical College.

NAPHTHOL is one of the remedies of recent introduction, and of the two products of that name the β naphthol is the one which was first used by Professor Kaposi as a substitute for the tar preparations in skin diseases. It was thought by him as the essential and curative ingredient of tar, while it was free from the objectionable features of the latter.

My attention was directed to this remedial agent by Dr. Justus Wolff, a chemist largely interested in the manufacture of coal-tar products, who kindly furnished me a paper on the chemistry of this substance, along with some novel properties which he had observed in it. As this paper, however, is too long for reproduction here in its entirety, and besides is largely of chemical interest only, I will here give it briefly in abstract as far as will be necessary to acquaint us with the chemical character of its subject, as follows:—

Naphthol is a derivative of naphthalene, a hydrocarbon found in large quantities in coal-tar, belonging to the so-called aromatic group. In the fractional distillation of coal-tar various hydrocarbons are obtained at different degrees of heat. Thus at 80° C. benzol distills over; between 80° and 110° C. benzol and toluol mixed; at 111° C. toluol alone; from 111° to 136° C. toluol and the different xylenes mixed; from 136° C. to 142° C. xylenes only; then the cumenes, phenol, and cresols; and at 218° C. naphthalene, which sublimes in colorless, transparent, brilliant, crystalline plates, possessed of a disagreeable pungent odor, the empirical formula of which is $C_{10}H_8$.

Naphthol is produced from this by a substitution of one of the hydrogens in naphthalene by one molecule of hydroxyl = OH.

According to the different positions of the hydrogen substituted in the naphthalene by the hydroxyl two different naphthols are obtained, of which one is called α naphthol, and the other, the one we shall alone speak of hereafter, is the β naphthol of the formula $C_{10}H_7OH$

The naphthols stand in the same relation to naphthalene as phenol to benzol and cresols to toluol. If one of the six hydrogens in benzol is substituted by hydroxyl, phenol is obtained; in the same way are cresols and naphthols formed. By this analogy of constitution of naphthols, phenol, and cresols, the inference may easily be arrived at, that they may prove alike in their disinfectant character as well, and in order to prove this I undertook a series of experiments. Of course the use of commercial naphthol for that purpose was out of the question, and I experimented, therefore, first to obtain a naphthol free from odor. As the crude article contains, as contaminations, sulphur and sulphurous acid, the sublimates thereof will yield, besides the naphthol crystals, also sulphureted hydrogen, thionaphtholes, carbolic and cresylic acid, thiophenols and the like, to which ordinary naphthol owes its pungent and disagreeable odor. I avoided this all by passing a rapid current of steam through its aqueous solution, expelling thus all volatile by-products, and ob-

¹ Read before the Philadelphia County Medical Society, October 17, 1883.

tained naphthol thus in its greatest state of purity, in beautiful silver crystalline scales, as here submitted. This naphthol may again be sublimed and obtained then in elegant white crystals as here shown, but by the heat employed more or less decomposition again takes place and renders the product somewhat odorous and pungent.

In order to test the disinfectant and antiseptic properties of my inodorous naphthol, I added one part thereof in powder form to 480 parts of urine, which at the expiration of six months, at a varying summer temperature, manifests no odor or signs of decomposition, while another of the same urine without addition of naphthol had a strong putrid odor already, after standing for three days only. To this latter I added, after standing thus for eight days, some of my inodorous powdered naphthol in the above-mentioned proportion, and in twenty-eight hours it had lost its putrid odor, and has kept thus up to the present writing, when no putrefaction or signs of it can be detected in either specimen. The same experience I have made with meat immersed in a solution of naphthol in 520 parts of water, as well in other experiments similarly conducted.

Experiments with solutions of the compounds of naphthols with alkalies or alkaline earths prove that these are very much less antiseptic than the solutions of pure naphthol soaps, containing four to ten per cent. of free naphthol, which were found excellent and serviceable in removing odors of putrefaction or decomposition from hands or cloths. They are also very efficacious in destroying clothes or body lice, as naphthol is a very active parasiticide. If naphthol is evaporated by means of heat, the air in rooms contaminated in consequence of disease or otherwise will be found to be rapidly deodorized and rendered fresh and sweet without other odors, making it thus of the greatest value for sick-rooms, hospital wards, dissecting rooms, etc.

As carbolic acid has many disadvantages, and is not the deodorant or antiseptic *par excellence*, the inodorous naphthol can certainly take its place in every respect. As naphthol has been described variously as poisonous and injurious to the animal economy, which by its composition and analogy was not apparent, I felt it my duty to experiment with it in regard to such, and commenced at once, without hesitation, by taking it internally; one part dissolved in 3000 parts of water produced at first heart-burn, a slight sensation in the right lumbar region, and some dizziness. Of that solution an equivalent amount was taken to represent a half grain.

These symptoms disappeared after continuing its use for some days, and while the urine showed, upon analysis, traces of naphthol and naphthol compounds, no albumen or blood could be detected therein. The doses then were gradually increased to four grains per day for six days, and still no untoward symptoms were discovered, while the warmth in the stomach directly after taking was followed by increased appetite. Dr. Schofield, of Albany, reports to me that upon my solicitation he has used it largely; at first experimentally in the Albany Hospital, where it has now become a staple article, and is used almost entirely to the exclusion of other disinfectants and antiseptics. They use it there for all kinds of disinfection in wards, sick-rooms, for wounds, etc., and have abandoned carbolic acid in all but a few cases, and always with the great-

est satisfaction and success. This far the paper of Dr. Wolff.

His experience, as well as that of Kaposi and others, led me, some eight or nine months ago, to employ it both in private and hospital practice, and the success attained with it soon led me to further experiments. I found it to fully sustain the claim that Kaposi had made for it in scabies, psoriasis, and chromophytosis, as well as in some of the chronic forms of eczema, in which it not only allayed the itching attendant thereto, but lessened the infiltration as well. In wounds and indolent ulcers I have found it a most useful detergent and deodorant, removing the fetor and establishing healthy action of the parts. Aqueous solutions, containing half a grain to the ounce, I have used to great advantage as vaginal injections, especially in leucorrhœa and uterine carcinoma, as well as in gonorrhœal affections both in male and female. In diphtheritic throat affections it made a most useful gargle, as well as to remove the fetor of catarrhal and other affections of the buccal cavity. Its greatest value, however, arose from its disinfectant action of the evacuation of fever patients and rooms containing them, while by its absence of odor it did not tend to produce inconvenience both to patient and attendants. Combined with powdered talcum or starch, or both, and dusted into the shoes or stockings of those affected with fetid exhalations of the feet it acts most satisfactorily, and its effects are equally as good in the same affection involving the hands, axillary, and inguinal regions. Combined with other ointments in the proportion of from one to ten grains to the ounce, it not alone preserves the unguent from decomposition, but exercises also an antiseptic action to the parts and the exudation therefrom. A slight admixture to an experimental sample of lard has preserved the same in excellent condition throughout the hot summer months. In chronic psoriasis, particularly when there is great infiltration, a five to fifteen per cent. ointment has frequently been attended with good results. It has also been very effective in squamous and fissured eczema used in combination with lard or gelatine.

To test for myself its antiseptic properties in comparison to that of carbolic acid, I mixed two whites of an egg with equal weight of water, and took one half of this mixture in one vial, adding one grain of crystallized carbolic acid, while to the other half in another vial I added one grain of Dr. Wolff's odorless naphthol. After the expiration of five days the carbolized albumen assumed a putrid odor, whereas the naphtholized part, though discolored by the naphthol, remains to this day, twenty days after the experiment, without odor. A quantity (about half pound) of meat already commencing to putrefy was also at the same date immersed in a saturated aqueous solution of naphthol, with the effect of arresting the putrefaction and preserving it for some time.

After using naphthol so long and successfully without any untoward occurrences, I read, to my astonishment and alarm, that Dr. A. Neisser, in the *Centralblatt für die medicinischen Wissenschaften*, 1881, No. 30, reported most extraordinary toxic effects obtained with naphthol, and that also Kaposi reported having seen hamaturia, ischuria, vomiting, unconsciousness, and eclamptic attacks in a boy after the external application of naphthol. Also that Squire reports, in the *British Medical Journal*, January 14, 1882, of it producing blisters and irritating the skin.

Dr. Piffard regards it as a dangerous remedy, and Professor Rapon, while he reports good results with it¹ in scabies, prurigo, and eczema, advises in prolonged cases simple ointment to be substituted every fourth week to avoid any possible risk of absorption.

Dr. Neisser stated that one gramme of a saturated solution (which in water would contain about one thirtieth grain of naphthol) injected hypodermically in a dog produced hæmoglobinuria, and shortly afterwards death.

To verify these accounts and satisfy myself on the toxic effect of pure naphthol, if any it possessed, I administered to one rabbit, repeatedly in twenty-four hours, thirty-four minims of a saturated aqueous solution, hypodermically, without any result, either to inconvenience the animal, increase his temperature, diminish his appetite, or cause lethal effect. This method of treatment was pursued for five days, not less than four to five injections being made per day, and the result was still the same. Determined to obtain toxic effects with it, and, if possible, to demonstrate its toxic action by a post-mortem examination, another rabbit was fed, at first every three hours, with one-grain pills of naphthol, and subsequently with two and four grain pills, at the same intervals, but, beyond increasing the appetite of the animal, no special effects were apparent. In consideration of this, one of my assistants, Dr. Charles S. Means, and my student, Mr. F. C. Waterman, volunteered to take naphthol themselves internally, to test, if possible, its action upon the human organism. They commenced with one quarter of a grain dose every two hours, their pulse, temperature, and urine being subjected to the closest inspection both before and after.

* The second day they took a half grain every two hours; the third, one grain every three hours; the same on the fourth, while on the fifth and sixth they took two grains every three hours, and on the seventh five grains twice daily. The pulse and temperature did not appear to be affected by this, nor was at any time albumen or blood apparent in the urine. Though they experienced great warmth in the epigastric region after each dose, that passed away in a short time, but left them with slight vertigo, buzzing of the ears, with all evidence of cerebral hyperæmia. The alvine evacuations were softened and of mushy consistence, changed to a clay color, and in one of the cases increased to diarrhœa.

Arriving at a résumé of my experiments, I must certainly proclaim the odorless naphthol which I had received from Dr. Wolff as not a toxic agent; and while I have found it a most useful remedial substance, and a disinfectant and antiseptic of the greatest value, it does not, in my experience, confirm the dangerous influence exercised on the human organism as reported by the gentlemen above quoted; a fact for which I can only account by the greater purity of the material used by me, — purified from the deleterious contaminations above enumerated by the process already described, which is not employed abroad, where yet naphthol is sold and used as reddish crystalline masses, with strong, pungent, and disagreeable odor. That it is far superior to carbolic acid and other disinfectants and antiseptics I have no doubt, and I am informed that in price it is not alone cheaper than the former, but, by its greater efficacy and smaller amount necessary, it is certainly more advantageous, aside from its greatest recommendation of being almost absolutely odorless. It must be

borne in mind that all my remarks apply to odorless naphthol, — only such as I have exhibited, — and that I consider that alone as safe for medicinal use.

RECENT PROGRESS IN PUBLIC HYGIENE AND STATE MEDICINE.

BY SAMUEL W. ABBOTT, M. D.,

Health Officer Massachusetts Board of Health, Lunacy, and Charity.

SEWERAGE AND SEWAGE DISPOSAL.

Sewage Utilization at Pullman, Ill. — The practical results of sewage farming at the town of Pullman, Ill., have been thus far unusually successful, and demonstrate the fact that under favorable conditions the work can be conducted in such a manner as to yield a fair profit on the investment. The town of Pullman has a population of 8000 or more. During the past season the sewage farm has been devoted to an experimental crop of a varied character. A general estimate is given as follows: —

Acres cultivated, 160.

Total investment, \$80,000.

Estimated cost of operating, \$8000.

Estimated value of crops, \$12,500.

Estimated profit beside taking care of the sewage of 8000 people, \$4500.

With longer experience and better appliances the superintendent believes he can considerably increase this profit in coming years.²

Sewerage of London. — Complaints having recently been made that the sewage of London, which is discharged into the Thames below the city, at Crossness and Barking Creek, has become a nuisance to the inhabitants dwelling near the outfalls, the Secretary of State has, in compliance with statutes, recommended the appointment of a royal commission to investigate the cause of complaint. A commission has, therefore, been appointed and instructed "to inquire into and report upon the system under which sewage is discharged into the Thames by the Metropolitan Board of Works, whether any evil effects result therefrom, and, in that case, what measures can be applied for remedying or preventing the same."

Sanitary measures have accomplished much toward reducing the mortality rate of the great metropolis in the past half century, and the report of this commission as a continuance of the same important service will be looked for with much interest.³

The Sanitary Works of Paris. — M. Durand Claye, the secretary of the recent Commission appointed to report upon the sanitation of Paris, has published a summary of the proceedings of the Commission.

Certain points of interest in this report show a decided inclination on the part of the majority of the Commission to adopt a general sewerage plan in place of the storage of filth which has long been tolerated throughout the city. (The traditional sewers of Paris are not sewers in the sense of conduits for the conveyance of household sewage.)

At its session of June 21st the Commission adopted several resolutions relating to the regulation of —

(1.) Water-closets, with their accompanying supplies of water, and the soil-pipes connected with them. Also the necessity of traps between each house and the sewer.

¹ Sanitary News, October 1, 1883.

² Report of Metropolitan Board of Works, May, 1883.

³ British Medical Journal, page 750.

(2.) Privy vaults, and the necessity of their discontinuance wherever connection could be made with the sewers.

(3.) The immediate abolition of *movable vaults* or tanks wherever it is possible, except where dry absorbents are carefully used.

(4.) Apparatus for separation and dilution. Contrivances of this sort, displaying but little ingenuity, have been in use for many years, subjecting basements and cellars to constant liability to foul stench from overflow and neglect. Their use is properly condemned, and the substitution of a water supply and sewer connection advised.

The management and care of the sewers occupies a portion of the report. Flush-tanks are advised adapted to sewers having a total length of 424 kilometres (262 miles), each flush-tank to hold ten cubic metres of water (2640 gallons).

The purification of the sewage is also mentioned as a matter of importance, and its treatment by soil irrigation upon land along the banks of the Seine advised as a process devoid of danger to the public health. The execution of the plan advised by the Commission will occupy several years. Thus far the Municipal Council have refused to appropriate the sum requested for these public works by M. Alphand, the president of the Commission.¹

The Sewerage of Chicago. — The proper disposal of the sewage of a large and level city like Chicago is not an easy problem. A peculiar feature in its present system is the Fullerton Avenue conduit, a large brick sewer in which the contents are compelled to flow in either direction, east or west, as occasion may require. This result is accomplished by means of a screw like a steamer's propeller working in the sewer with a capacity of 24,000 cubic feet per minute at 100 revolutions. At one end the outlet is into the river (North Branch), and at the other into the lake. The city water supply is drawn from the lake at a point in doubtful proximity to the sewer outlet. During the greater part of 1881 the sewage was forced into the lake, and as a consequence "the effect upon the water supply was painfully apparent during the greater part of the year notwithstanding the claims of the authorities that the sewage thus forced into the lake through the conduit obligingly flowed off in a northwesterly direction or south along the shore. The water given the city to drink was plainly contaminated by sewage. The underground communication between lake and river still continues its misdirected mission of conveying sewage from the latter to the former, and the lake shore is washed with the black and decomposing waste of thousands of distilleries, factories, stables, and houses. Where this conduit operates, as was originally intended, from lake to river it serves a useful purpose."²

Bunzlau. — As a contribution to the history of sewerage and sewage disposal, the recent Hygienic Exposition at Berlin has brought to light the fact that Bunzlau, a small town in Silesia, of 8000 inhabitants, has had for more than three centuries (since 1559) a complete system of water supply, sewerage, and sewage utilization by surface irrigation. In an ancient chronicle of 1538 the advantages accruing to the town from its water supply are detailed as follows: —

- (1.) To quench the thirst of man and beast.
- (2.) To bleach linen.

(3.) To preserve live fish in tanks.

(4.) To run mills.

(5.) To cook and brew beer.

(6.) To wash and bathe.

(7.) To carry away the impurities of the soil.

(8.) To irrigate gardens and fields.

The larger sewers are chiefly rectangular, and built of slabs, and are of ample dimensions.

The first attempt at sewage irrigation by this town was made in 1559, and was quite successful in its operation. At a later period each farmer was given the use of the sewage for certain hours, varying from two to four hours per week. The sewage is distributed in open trenches.³

Filtration. — A recent improvement in the filtration of sewage or of any liquids containing solid matter, is the Farquhar filter, an apparatus which claims the following advantages: —

(1.) Economy of labor.

(2.) Large volumes of liquid can be filtered continuously, and in a short space of time.

(3.) Economy of material.

(4.) Absolute limpidity of liquids filtered.

The deposit of a layer of solid material upon the upper surface of filter-beds has thus far proved a serious difficulty, much time and labor being required to remove the deposit and prevent clogging. The Farquhar filter overcomes this obstacle. Its construction briefly stated is as follows: A closed iron tank or cylinder containing a quantity of sawdust, charcoal, or other porous material. A revolving iron plate carrying a knife or scraper continually removes the deposit from the upper surface of the filtering material, and leaves it in the upper part of the cylinder, from which it may be removed as often as necessary. The liquid to be filtered is admitted from above under pressure, and the clear liquid flows out below. The capacity of the Farquhar filter has recently been tested experimentally, at the Mystic Valley sewer, through which flows an offensive, turbid, chocolate-colored sewage; its solid residue comprising the waste products of the tanneries of Woburn and Winchester. Its final success in treating this sewage remains to be proven. It has been treated during the past season in a series of shallow settling-basins, which removed a portion only of the solids.

FOOD AND DRUGS.

Vanillism. — Under this title Drs. Layet and Arnoz have communicated to the French Association for the Advancement of Science the results of certain researches relating to the physical qualities, the effects, and the parasites of vanilla. Several cases of poisoning by the eating of vanilla ices and ice-creams are cited. At first the analyst had decided that the poisoning was due to the formation of lactate of tin in the vessels which were used in the process of preparation. But the confectioner having been obliged to abandon his business in consequence of the disturbance which followed the poisoning, his stock of vanilla was sold to a confectioner in another city, and cases of poisoning again followed its use. Other cases were also observed in Berlin.

The symptoms were much like those of cholera, — continued vomiting, frequent diarrhoea, epigastric pain, cramps in the legs, extremities and face cold and purple. Recovery in three or four hours after the onset

¹ Revue d'Hygiene, September, 1883.

² Sanitary News, October 1, 1883.

³ Sanitary Engineer October 4, 1883.

of symptoms, which usually take place in less than two hours after eating the *glace*. The same result has been noticed after eating other preparations in which vanilla had been used.

Other disturbances due to the handling of vanilla are also reported as occurring among operatives who cut the vanilla pods in small pieces. These disturbances consist in papular eruptions of the face and hands, with heat and swelling of the parts affected, pruritus, and irritation of the eyelids and the eyes, the eruption often attended with patches of redness and desquamation.

Bordeaux produces at present a crop of about 23,000 kilos. (50,000 pounds) of vanilla per year.

Infernal Machines in Beef.—In labeling pieces of meat for customers, butchers and others have found a very convenient article, which may be termed a barbed wire staple. The paper label is laid upon the meat and the pointed staple driven through it into the meat. Occasionally the paper becomes detached, leaving the staple in the beef. As a consequence two cases of œsophagotomy were recently reported from Philadelphia hospitals. A patient in a Massachusetts institution also found one of these hooks in her mouth while eating meat.

At a recent meeting of the Philadelphia County Medical Society the danger apprehended from these "skewers" was referred to as being overestimated. Possibly a few more cases of œsophagotomy may be necessary to illustrate their relation to hospital practice.

For convenience in identifying this barbarous implement the accompanying cut shows its shape and dimensions. Width 12 mm. Length 18 mm.

It is made of stiff iron wire; each point is quite sharp, and barbed like a fish-hook. They have been found in canned beef as well as in fresh meat.

Milk Inspection in Zurich.—In reply to inquiries as to the milk inspection in Zurich, Alderman F. Schlatter states that the work is intrusted to the care of a health commissioner and health inspectors or police. Analyses are made by two chemists, one for the city and another for the canton, acting independently of each other.

Inspections are made at early morning, without regularity as to time and place.

The instruments used by inspectors are a thermometer, a lactometer (Muller-Quevenne's), and a stand-glass. Milkmen are required to register and receive a license. They are to be treated uniformly, but not in regular order, a dozen or more tests to be made for each one.

Inspections are not made in a crowded street, but samples are taken to a neighboring police station, shop, or bakery, and a small fee paid to the proprietor for its use.

Punishments are provided for adulteration and for repetition of the act. Appeals to higher courts are also allowed.

In a population of 76,000 (26,000 in the city and the remainder in its suburbs) 12,500 litres of milk were daily sold in 1882. Two thousand one hundred samples were inspected as to their appearance, taste, and specific gravity, of which number 226 were analyzed by the chemists. Thirty-seven were punished.

In summing up the writer evidently believes that more efficient work might be done with more hearty coöperation on the part of the higher authorities, and suggests the publication of names as an additional measure.

The local regulations recognize two grades of milk, whole milk and skimmed milk (*halbabgerahmte milch*), the latter being defined in the statute as a mixture of equal parts of skimmed evening milk and whole morning milk.

The whole milk must show a specific gravity before skimming of from 1029 to 1035, and after skimming not less than 1033. The chemical analysis must give at least twelve per cent. of solids, including three per cent. of fat.

The *mixed milk*¹ must show a specific gravity before skimming of 1030 to 1036, and after skimming not less than 1033. Its analysis must give at least eleven per cent. of total solids, and 2.3 per cent. of fat. The two sorts of milk must have distinguishing labels upon the milk-cans.

INFECTIOUS DISEASES.

Typhoid Fever of Faecal Origin.—M. de Henry communicates to the Society of Public Hygiene of Bordeaux two series of cases of typhoid fever in which contaminated drinking-water was the medium of communication. In the village of Chez-Ganivet twenty-two people were attacked, and in this group the soiled linen of some patients ill with typhoid fever had been washed in a spring which was used for drinking purposes. In the second series an epidemic occurred in a prison at Ha, the convicts only in a certain quarter being attacked, thirty-nine in all. The prisoners awaiting trial, and also the women, in other parts of the prison all escaped infection. On inquiry it appeared that the water supply for the exclusive use of the convicts was pumped from a cistern in the court-yard. The convicts, after emptying their stool-buckets, came to this cistern and rinsed them, throwing the water on the ground, whence it doubtless made its way into the cistern. The other inmates of the prison obtained their water supply elsewhere.²

The Typhoid Epidemic of Paris.—Professor Pagliani, of Turin, in commenting upon the prevalence of typhoid fever in Paris, rejects the theory advanced by Virchow that rain-water, impregnating the soil, favors decomposition and the development of typhoid germs, and states his own proposition as follows: "Whenever heavy showers of rain fall, especially in torrents, as often happens in Paris, the volume of water in the great sewers increases in an extraordinary manner, and causes stagnation or rather regurgitation in the smaller conduits which connect inhabited dwellings with the principal sewers."

The rush of great volumes of water into the sewers stirs up the mud and filth which are deposited in seasons of dry weather, and the effluvia set free finds vent at the points of least pressure, the soil-pipes, water conductors, etc.

The writer shows that typhoid fever has prevailed most in those parts of the city where the foregoing conditions are found. He also adds the following proposition: "The number of cases observed is not in proportion to the quantity of water which falls upon

¹ Deutsche Vierteljahrsschrift für öffentliche Gesundheitspflege. 15 B. 3 H. 1883.

² Gazette Hebdomadaire des Sciences Med. de Bordeaux, 1883, page 188.

the ground, but to the quantity and probably to the quality of the gases (miasmas) set free and forced back toward the neighboring dwellings."

Epidemics arising from similar causes are quoted, that of Cologne, reported by Eulenberg as due to the obliteration of a sewer by the freezing of the Rhine; others, in Brussels and in Naples, due to choking of sewers in time of violent storms.

The conclusions of Professor Pagliani are in favor of an adoption of movable receptacles, and the complete removal of their contents for the benefit of agriculture, or the adoption of the pneumatic system of Liernur.¹

Vaccine and Variola.—A series of papers by Dr. Leonhard Voigt upon the relations of variola to vaccinia are given as the result of many years' experience and observation, and the following essential points enumerated.

As the practice of animal vaccination has been conducted quite extensively in the United States during the past ten years or more, and the opinions of animal vaccinators have been freely expressed upon the same subject, a different conclusion has been drawn, especially as to the eighth and ninth propositions of the writer.

(1.) Vaccine lymph may be procured by vaccination of the cow with lymph taken from the pustules of persons sick with small-pox. But no one can be sure that every attempt will be successful.

(2.) The vaccine obtained in such a manner is suitable for the vaccination of men on account of the energy of its operation, but it should only be used after transmission from animal to animal several times, by which proceeding its effect is mitigated.

(3.) In the first year of its use vaccine lymph obtained in this way possesses a higher efficiency than an animal stock several years old.

(By this term, a *stock several years old*, we should understand lymph transmitted from animal to animal, at the time of the maturity of the vesicle, for several years. In accordance with the custom of animal vaccinators each year would represent a series of fifty-two to sixty-five animals, the period of maturity presenting slight variations.)

(4.) Vaccinia and variola originate in the same virus, and each gives to the person attacked a certain claim of immunity against suffering arising from the same source.

(5.) The duration of this immunity is in proportion to the intensity of the attack.

(6.) Among people who have had the small-pox twelve years before, we find almost the same susceptibility to vaccination as among those who were vaccinated at the same time. Consequently children twelve years of age, and vaccinated during the first year, are liable again to take small-pox.

(7.) Therefore, the imperial vaccination law which orders the vaccination of infants and their re-vaccination at twelve years of age fulfills an actual necessity.

(8.) Animal lymph transmitted from calf to calf, and originally very active, loses its power earlier than humanized vaccine transmitted from arm to arm. Humanized lymph gives the best results in men and animals in the long run; therefore the animal vaccine of old stock promises inferior results to retro-vaccination of the first remove.

(9.) Lymph carefully propagated, and originated from the cow-pox but a short time before, is the most efficient, not only in its animal but especially in its humanized form. Therefore resort should frequently be made to the original cow-pox in order to obtain lymph as protective as possible.²

Antiseptics.—In some researches on the aseptic power of certain substances with reference to bacteria M. Miguel publishes a table in which is given the weight of each substance required to render imputrescible a litre of beef soup (bouillon de bœuf).

We give a portion of the table in the order in which they are published:—

	Grammes.
Biniodide of mercury	0.025
Bichloride of mercury	0.07
Nitrate of silver	0.08
Iodine	0.25
Chlorine gas	0.25
Bromine	0.60
Sulphate of copper	0.90
Salicylic acid	1
Benzoic acid	1.10
Mineral acids	2 to 3
Essence of bitter almonds	3.20
Carbolic acid	3.20
Permanganate of potash	3.50
Arsenious acid	6.00
Hydrate of chloral	9.50
Salicylate of soda	10
Sulphate of iron	11
Borax	70
Iodide of potassium	140
Glycerine	225
Hyposulphite of soda	275

To prevent the dispersion of microbes from the sick he advises treating the dejections of patients with the following solution:—

Sulphate of copper	20 grammes.
Sulphuric acid (66°)	40 grammes.
Water	1000 grammes.

Also the bathing of the bodies of patients with a solution of iodine 1 part to 1000, or of bichloride of mercury 1 to 5000.

VITAL STATISTICS.

In commenting upon the valuable reports of the British Registrar-General, a modern writer (Dr. Rumsey) styles them the first text-books in the study of hygiene.

The series of Registration Reports of Massachusetts have reached their present stage of perfection only through a gradual introduction of successive features, authorized by efficient legislation.

Michigan, Vermont, and several other States have for several years conducted a similar work, and New York is about to inaugurate the work of registration for its large population. A uniform plan or system adopted by all the States would afford a combined result of great value.

A series of papers on Vital Statistics recently begun in the *Sanitary Engineer* by Dr. John S. Billings, U. S. A., will be welcomed as a valuable contribution to this department of State medicine. The first paper is mainly definitive, and gives the meaning of the terms mortality rates, expectation of life, mean duration of life, probable duration of life, and specific intensity of life. In the second paper he discusses the question of the probable and possible errors and variations in statistics, independent of the accuracy of their data or of their relations to sanitary condition.

¹ *Giornale della R. Società Italiana d'Igiene*, 1883, page 298.

² *Vierteijahrschrift f. öff. Gesund.*, 15 B., 3 H., 1883.

The frequent publication of information relating to this important subject and its general diffusion amongst professional men is desirable, that every physician who has to do with the initial and the final stages of human life may recognize the necessity of making careful records of all essential data, and of contributing his individual share to the common welfare of the State.

Reports of Societies.

PROCEEDINGS OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

R. M. BUCKINGHAM, M. D., SECRETARY.

OCTOBER 22, 1883. DR. CHARLES D. HOMANS presided.

DR. JOHN HOMANS read a paper on

TWO-HORNED UTERUS (UTERUS BICORNIS). THE LEFT HORN NOT COMMUNICATING WITH THE VAGINA. SUPRAVAGINAL REMOVAL OF UTERUS, FALLOPIAN TUBES, AND OVARIES. CURE.¹

DR. HOMANS spoke of the value of auscultation. When the aorta can be heard the tumor is generally ovarian. This patient was eighteen years old, and well and strong. Operations have been commonly done as a last resort on feeble patients.

DR. J. P. REYNOLDS had listened with deep interest to this remarkable case. Beside the intrinsic importance of the record such histories are also of great value to the profession here and everywhere in the increase of courage that they bring to those who hope to find in a new appreciation of Cæsarean section, in Porro's operation, or in its modifications, chance of escape from the horrors and the disgrace of craniotomy. The resort to the latter dreadful alternative implies for the obstetrician an admission that his work has failed. The statistics, inestimable in worth, which our countryman, Dr. Robert P. Harris, has with conscientious toil laid before the profession, bid fair to compel us to rewrite the history of operative obstetrics. What may not be hoped for our art provided Dr. Harris's teaching as to the paramount importance of timely resort to operative measures becomes generally appreciated by medical men, while at the same time successes like that reported to-night have trained up in one community and another surgeons who when called will be found equipped for the work.

May we, if the demand comes, be enabled to add from this neighborhood yet one more triumph like that which Dr. Eliot Richardson, in Baltimore, has within a few months achieved. Each such instance brings help to many others beside those whom it immediately concerns. Dr. Homans' case is unique, and it is matter for congratulation that such an operation can be done in our neighborhood.

DR. W. E. BOARDMAN had never met with a report of a case of the kind, and was left to inquire if in future, if the diagnosis were made, the surgeon would feel authorized to attempt removal. There have been, perhaps, a dozen cases similar to this one which have been recognized during life, and have been relieved by opening from the vagina or rectum. The tumor projects into the vagina or parallel with it, and that is given as one of the diagnostic marks. Many cases of

hæmatometra with atresia vaginæ have been relieved by an artificial vagina, and these patients have menstruated, and have, if he is not mistaken, borne children. He did not raise the question as a criticism of the paper, but for the purpose of starting discussion, and he expressed no opinion himself.

DR. BLODGETT's report sustains the general statements of writers as to the conditions found in the anomaly. The bearing of the case on the study of menstruation is noticeable. Here the tube had no communication with the uterus, but nevertheless contained grumous matter pointing to the probability of menstruation. There is every reason to suppose it came from the tube in which it was found. The question of development forms an interesting study, and every case may contribute much towards the solution of the inquiries as to their diagnosis and treatment. In the only case of the kind met with by the speaker the vagina was double, the larger sac being blind. The patient applied for the relief of sterility, coition having taken place in the blind opening.

DR. REYNOLDS, while admitting, as he thought every one must, the very exceptional character of the case, asked if the account of it did not show that an opening into the vagina would have failed to give relief. The second sac, having no connection with the enlarged horn, already torn at one point, and discharging into the peritonæum, could not possibly be reached.

DR. BOARDMAN thought it did in this case, but that it is an extreme one, and could not have been recognized. He thought most surgeons would hesitate, and asked the reader what would be his course should he meet a similar case, and make a diagnosis of occluded horn.

DR. HOMANS said it is a hard question to answer without more study. Much of the success depends on the completeness of antiseptic precautions, which are hard to carry out in a wound opening into a mucous cavity. He could not reach the os, and the tissues through which a drainage tube would have passed were thick. The tube must be large, ought to be a double current tube, with the end in a vessel of carbolic acid, and must be sewed in. He should have expected a long, tedious convalescence, with rises of temperature. Then the artificial opening would probably close on withdrawal of the tube, leaving the patient as badly off as before. If the uterus had been distended and elastic, with a well-marked presentation of the os, he thinks tapping through the vagina might, perhaps, be the better operation. He did not know anything more before the abdominal section was made than that he had a thick-walled tumor full of fluid to deal with. He does not think aspiration of ovarian tumors through the vagina a particularly fortunate operation, and puncturing the imperforate hymen has often been fatal. Having punctured and got a slow recovery you cannot then change the operation. He thinks acting on surgical principles and succeeding points to an operation as a good one.

To a question of Dr. Boardman's he answered that the tumor formed a globular mass one and one half inches within the vulva. If he felt sure of succeeding in another case like this one he would adopt the same method.

DR. BOARDMAN said that although in cases of atresia of the genital tract where puncture has been made through the rectum the results have often been fatal from septicæmia, yet that good results have been ob-

¹ Vide page 436 of this number of the JOURNAL.

tained by making the opening through the vagina, and especially by the rapid operation as practiced by Dr. Emmet.

MANIA. RUPTURED CERVIX UTERI.

DR. W. F. WHITNEY presented a uterus removed nineteen hours after delivery. In the absence of the attending physician he gave the history. Maniacal symptoms came on during labor, for which turning was resorted to. There was some hæmorrhage easily controlled, mania continued, and the patient died. The uterus was torn from the external to the internal os, but the tear did not extend into the peritonæum. The cause of death was in the head.

DR. C. E. STEDMAN had seen a case of placenta prævia at the seventh month. During labor the patient, a healthy young woman, with her second child, became violently maniacal, and died shortly after the death of a putrid child. There was no great loss of blood. There was no autopsy. There had been no symptom of brain disease, the only trouble being that after the first hæmorrhage, a month before, she could not be kept still, but so good was her general health, she had made a visit in the country contrary to advice.

Recent Literature.

The Diseases of Women. A Manual for Physicians and Students. By HENRY FRITSCH, M. D. Translated by ISIDOR FURST. New York: William Wood & Co. 1883.

This is the March issue of Wood's Library of Standard Medical Authors, and is fairly up to the standard of the other works of this and former similar series. Following, so soon, however, after Hart and Barbour's *Manual of Gynæcology*, which appeared in January and February, it suffers decidedly by comparison with that original and interesting work. This is commonplace, and while there is very little to object to in its pages yet it hardly marks an advance in this branch of literature. It presents so little that is new that one scarcely understands its *raison d'être*. We could mention a dozen similar books, any one of which would be as valuable to the physician and student as this.

The fact that there are so many works which profess to cover the whole ground of gynæcology within a few hundred pages, and which do it fairly well, would we should think lead the surgeon who is anxious to write something of service to the profession to investigate thoroughly and minutely some special subjects which are still obscure. However, the book being here, it is our province to criticise it. We regret not to have seen the original German edition, so as to have been able to judge of its style. As translated the sentences are in many instances anything but models of correct English. They plainly betray their origin, being often Anglicized German rather than English, and this fault we mistrust must be charged to the translator. As for the subject matter itself it does not need any extended criticism. The whole realm of gynæcology is tersely but thoroughly surveyed, and the views advanced are in the main sound. The author is on the whole conservative, so much so in fact that he hardly does justice to the recent advances that gynæcology has made in America. A few of the more salient points of criticism may be briefly mentioned. We thoroughly agree

with the author in his statement that sponge tents should be abandoned. When we have other substances which will answer the purpose perfectly well there is no excuse for using so dangerous a method of treatment. We are surprised that he should consider puncturing the cervix with the bistoury as effectual in depleting the cervix as leeches. Certainly the latter deplete a much larger area, and follow nature's method more nearly.

When speaking of chronic catarrh of the bladder he does not mention that most valuable method of cure, namely, the formation of an artificial vesico-vaginal fistula, this securing thorough drainage and perfect rest for the bladder. As he does not recognize laceration of the cervix as a fruitful source of erosions of the cervix, he naturally does not mention the repair of the laceration as a method of cure, but advocates cauterizations with nitric acid.

His views as to displacements and their relief by pessaries are in the main good, but we fail to see evidence for his statement that anteversion is always a sequel or accompaniment of metritis or perimetritis. Nor do we think he has the right view of the action of the Hodge pessary, as he evidently thinks it acts by stretching the vagina, and not as a lever. He condemns the use of elastic rubber rings in cases of prolapse, but advocates using them for versions and flexions. The same arguments against employing them would hold equally good in the latter case.

The chapter on parametritis and perimetritis is very good.

Diagrams for Recording Diseases of the Ear. A. E. Wilde & Co. Cincinnati.

A series of diagrams, each containing three plates, one of the membrana tympani with the manubrium, short process, anterior and posterior folds and long arm of the incus, shown in outline, one of a perpendicular section of the whole ear, and one of a horizontal section of the whole ear, with the mastoid cells. These diagrams, which are drawn in outline, are made for both right and left ears, and will prove valuable for sketching the various pathological conditions with which the surgeon has to deal, and which it is often impossible to retain in the memory or describe readily in words. It is carrying out for the ear what has been done for the eye, chest, and abdomen, with similar outlines, and gives the surgeon a quick and easy method of making important records. The execution of the plates is good and seems to leave nothing to be desired.

A History of Tuberculosis from the Time of Syllivius to the Present Day, being in Part a Translation, with Notes and Additions, from the German of Dr. Arnold Spina, containing also an Account of the Researches and Discoveries of Dr. Robert Koch and other Recent Investigators. By ERIC E. SATTLER, M. D. Cincinnati. 1883. 191 pages.

This book will be chiefly of value to those who wish to gain a clear idea of the work which has been done on the question of the inoculability of tuberculosis and its parasitic origin. There is nothing of original research in the book, but it is fairly well up to the latest advances which have been made. Although endeavoring to present an impartial statement of the subject the author is inclined to doubt the value of Koch's discoveries.

Medical and Surgical Journal.

THURSDAY, NOVEMBER 8, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft or registered letter.

HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

ALASKA FROM A MEDICAL POINT OF VIEW.

IN the year 1881 the United States Revenue Cutter Corwin made a cruise to Alaska and the Arctic Ocean on its relief expedition to the Signal Station at St. Michael's. On this voyage many facts of scientific interest were observed and recorded. Among them the observations of Dr. Irving C. Rosse, of a medical and anthropological nature, are deserving of special mention both from the intrinsic value of their subject-matter and on account of the charmingly entertaining style in which they are communicated. The facts remarked by Dr. Rosse may be classified according as they concern the effects produced upon the visitors by the peculiar conditions under which they found themselves, and those phenomena observed among the aboriginal inhabitants, due in part to those same conditions, become permanent, and in part, of course, to race idiosyncrasies.

Under the former heading we notice with interest that a discrepancy was often observed between the record of the thermometer and the feeling of the observer, or, as the writer expresses it, between physical cold and physiological cold. With the thermometer at 45° F. the temperature was described as "murky," and again at 60° F. the direct sun heat was once "almost overpowering." Whereas the experience of travelers in other latitudes, as, for example, in the Peruvian Andes, is cited as showing a keen and penetrating cold at the same temperature, 60° F. As Dr. Hayes went in swimming in a pool of water on top of an iceberg in Greenland, and as other northern travelers have bathed in Siberian waters, so our writer took his plunge into the icy arctic sea on one of the "physiologically warm" days, and enjoyed it. The whole subject of heat production and temperature equilibrium among northern peoples as well as in the marine mammalia is one of exceeding interest, and the reported facts of a physiological rise of temperature after exposure to cold water or air in temperate climes may possibly indicate some special adaptation of thermic functions in these hyperboreans. At all events it is much to be regretted that the only clinical thermometer carried by the expedition was broken so early as to prevent any observations being made on the temperature of the human subject under varying conditions; especially unfortunate is it in view of the author's suggestions as to the value of alcoholic beverages in cold climates. Contrary to the teaching of

physiology regarding the vaso-motor effects of alcohol, and contrary also to what has been often claimed, as in a recent paper by Dr. Leffmann before the Philadelphia County Medical Society, to be the experience of arctic explorers of the deleterious influence of alcohol among northern voyagers, we find that Dr. Rosse cites numerous arctic travelers, and coincides with their testimony, to the effect that the moderate use of alcoholic beverages is found to be advantageous in the extreme weather of the high latitudes. But it is possible that the discrepancy is more apparent than real, for we have no thermometric records on the spot to offset the physiological evidence, while alcohol seems to be one of the best antiscorbutics, and we know scurvy to be one of the great banes of northern voyagers. The "heavy-headed revel" which Hamlet confessed his countrymen to be addicted to, and to which travelers in general have observed a tendency in northern peoples, may be, as our author rather intimates, but nature's call for a protective against the inclement conditions of life, but if so, nature seems in some danger of over-doing the matter, for we read of the rapid depopulation of St. Lawrence Island, where one thousand of the inhabitants have perished in three years, and many villages are already quite extinct, a result ascribed to too much of the "bay rum," "Florida water," and other euphonious brands of poor alcohol which struggle past the revenue officers, and for which the Esquimaux exchange their furs with great eagerness. Of course much of the responsibility for this physical deterioration ascribed to intemperance properly belongs to the vile liquors used, and again to starvation. But certainly more exact observations as to the effects of alcohol in the human economy in cold climates are much to be desired.

The northern voyager seems to be, as a rule, tolerably free from acute bronchial or pulmonary disorders while exposed to severe cold, but there is a marked tendency to the development of such affections after his return to a temperate climate. This was observed in the crew of the Corwin, as it has been in other individuals. On the other hand the natives seemed constantly suffering from colds and coughs, a fact which appears to show a greater cold-resisting power in the white race.

Some curious optic and auditory phenomena are recorded. The irregular refraction of the atmosphere at some points, taken in connection with its wonderful clearness in others, gives rise to remarkable deceptions of the vision. The distinctness with which small stones and other objects on a mountain side can be seen at times bewilders the vision, while the vagaries of the mirage and the blending of the real with the unreal leaves one in doubt as to what he actually sees. The sound of a boatswain's orders and of laughter and loud conversation at the distance of two miles, the noise of one's own beating arteries on a still day, and the repetition of echoes, in one case to one hundred times after a pistol-shot, are some of the freaks of acoustics.

The diseases to which the native Esquimaux are specially subject are scurvy, syphilis, and an epidemic which is described at length, and which seems to have

been a species of pneumonia of an extremely asthenic type. No post-mortem evidence was at hand to show whether the pathological condition corresponded with that of the type of the disease common with us. Lung troubles in general seem to follow a mild winter. Intermittent fever at Cook's Inlet, apparently originating on a bluff several hundred feet high, in houses exposed to a breeze direct from the inlet, is a fact more interesting than explicable. Rheumatism and gastric derangement, the latter due often to over-eating, are not rare.

Alaska is a favorable place for surgical operations, wounds healing with great rapidity. The presence of ozone and the absence of "germs" are believed to be the cause of this. Hysteria is a luxury which the female Esquimaux is by no means willing to relinquish entirely to her white sister, and nervous diseases we find to be quite frequent. Our author, with much less leniency for the narcotic weed than for alcohol, ascribes neurotic diseases to "that senseless and filthy habit, the use of tobacco." Certainly they can hardly be considered as the sequelæ of civilization.

Much of interest is told of the social, ethnographic, and other peculiarities of the Esquimaux, which space forbids us to allude to. We may merely mention that the popular notion of the typical Esquimaux cranium is said by Dr. Rosse to be incorrect. Instead of the pyramidal skull, with prominent superciliary ridges, occipital protuberance, and zygomatic arches, and with small brain capacity, one finds the type to have a large facial angle (eighty degrees), and a brain capacity equal to the average Frenchman or German. The squamo-parietal suture has not the convexity noticed in the chimpanzee and the Mound Builder, and the index of the foramen magnum is about the same as in European crania. According to Dr. Rosse the facts regarding the natural intelligence of the Esquimaux correspond with these cranial appearances, and the northern people have by no means the dullness and slowness of understanding which some have ascribed to them. Neither have they any coldness of the passions corresponding to the thermometric range of their climate. Unchastity is as common among them as among the hottest savage that swelters under the tropic sun, and it is evident that something more than external ice and snow are necessary to cool the desires of the human animal.

THE MEDICAL TREATMENT OF INSANITY.

DR. BROSIUS, superintendent of a private asylum at Bendorf, in Germany, and editor of the *Irrenfreund*, goes into this subject in a recent number of the *Allgemeine Zeitschrift für Psychiatrie*. He has already had something to say concerning his lack of confidence in remedies intended to cure the insane, in a paper entitled *Aus Meiner Psychiatrischen Wirksamkeit*. Boerner and recently Schüle have taken very nearly the opposite view of the matter. At Illenau (Schüle's asylum) morphia has been used for many years in immense quantities, and the recoveries have risen from

thirty-six to 39.9 per cent., and deaths have fallen from twenty-five to 15.2 per cent. These cures are not, however, ascribed to morphia, but to the more frequent admission of curable cases.¹

Where sedatives are used in asylums, we have a variety of agencies at work, and it is hard to say that any one medicine has produced a cure. When one sees the great influence of time, and plenty of food, and good hygienic surroundings on the insane, and sees the worst cases recover without medicine, it is difficult to say where medicine has been used in similar cases that it has been instrumental in effecting the cure.

The French physicians many years ago recognized the harmlessness of the expectant treatment, and they gave up depleting forms of treatment before narcotics had become fashionable.

Among the German psychiatrists fifty years ago at Marsburg the treatment of the insane without medicine was agitated. Tigges, Reissner, Leidesdorf, and Reimer seem to have little confidence in opium either in melancholia or any other form of insanity.

In England the feeling against narcotics increases steadily, and is more and more outspoken. As long ago as 1871 Blandford spoke against opium, and especially subcutaneous injections of morphia. In the same year Maudsley addressed the Medico-Psychological Society on the Use and Abuse of Sedatives. Dr. Clouston's researches seemed to show that opium was a dangerous remedy. He thought that sedatives were beneficial if they allayed excitement. This was the question. Dr. Yellowlees did not doubt the value of sedatives, but rarely used them. He regarded the treatment of the general disturbance as of greater importance than the fighting of the excitement.

In 1875 the French Medico-Psychological Society discussed the treatment of melancholia by morphia, Voisin reading a paper favorable to this treatment. But few of those present took the same ground, and Christian thought many cases so treated relapsed sooner.

In the cases of "dysphrenia neuralgica" which Schüle reports, treated with morphia, the length of the attacks was so great that morphia could not be regarded as having shortened the attack. If general experience shows cases to be so long getting well that are treated with morphia, it must be regarded as a retarding influence, in the opinion of Dr. Brosius. As yet, he concludes, we can only say that narcotics are valuable to overcome symptoms.

Krafft-Ebing,² on the other hand, is a very strong advocate of opium, and favors the use of the aqueous extract subcutaneously in a solution of one to twenty. Opium, he says, acts (1) by quieting the cerebral hyperæsthesia and precordial distress, and is also hypnotic; (2) it stimulates the vaso-motor nerves, and thereby causes contraction of blood-vessels; and (3) it has a tonic effect on the central nervous system, and improves its nourishment. When the proper conditions exist a bad effect is seldom seen. It is of priceless value in beginning melancholia; even when the dis-

¹ Band xxxix., Heft 2 and 3. Zur Frage der Medicamentösen Behandlung der Psychosen.

² Lehrbuch der Psychiatrie, page 254, et seq.

case is at its height it often cures. It is useful in anæmic, hysterical, and hypochondriacal conditions. It is also valuable in the acute alcohol psychoses, delirium tremens, and some forms of delirious mania. The dose is from one fiftieth to one tenth of a gramme. Morphia produces many of the effects of opium, but is not so good where the vitality is much depressed.

Dr. Rudolph Arndt,¹ in his recent text-book, speaks very cautiously of narcotics, especially of opium, which should not be used longer than eight days unless some good results follow. He mentions Chiarugi, Guislain, La Grand du Saulle, Schröder, Van der Kolk, Griesinger, Schüle, Mendel, and others as advocates of opium, but thinks in many of the cases of recovery the same result would have been accomplished without the drug. According to his ideas the narcotics are *poisons*, which, given for long periods of time and in large doses, may produce the most injurious results. It will be better when possible not to resort to their use.

Dr. Mendel² does not believe in morphia for mania, but says that it produces so marked a quieting effect in melancholia agitata, that it is almost pathognomonic of this disease.

MEDICAL NOTES.

— Any person having purchased a copy of the United States Pharmacopœia of 1880, and desiring a list of the corrections since made therein, can procure the same by sending a two-cent stamp to William Wood & Co., Publishers, 56 and 58 Lafayette Place, New York.

— By invitation of Dr. H. W. Williams, the annual meeting of the Massachusetts Medical Benevolent Society was held at his house, No. 15 Arlington Street, last Thursday. The meeting was well attended, and offered, as usual, many enjoyable social features.

— We notice the suggestion that an easily adjustable handle for the laryngoscopic and rhinoscopic mirror, as well as the laryngeal probe, is the ordinary automatic pencil holder made by the Eagle Pencil Company, and sold by stationers generally. The handle of the mirror is held in place in the same manner as the lead, and can be lengthened or shortened by pressure on the spring at the end of the holder. After several months' trial it has been found most satisfactory, from its smoothness, and the short time required to adjust it.

— In regard to the prevalence of typhoid and malarial fevers in Connecticut the secretary of the State Board of Health, in his report for September, says: "The increase in the prevalence of typhoid fever is seen forcibly when the mortality is compared with that from malarial fevers. Thus in the present year the deaths in the cities reported are, from typhoid fever, twenty-three; all varieties of malarial, eight. In 1882, typhoid fever, twenty-one; malarial, twenty-three. In 1881, typhoid, seven; malarial, eighteen (this is for September). The decrease in the mortality from

malarial fever is quite regular. It is true that the total from typhoid is increased by its prevalence in Waterbury, but in quite a large area the reports show a similar increase of typhoid and decrease of malarial fevers. In Waterbury malarial diseases never have been the governing type as far as I can learn. The amount of typhoid fever in Waterbury has, as is usually the case, been exaggerated. The dry weather, low water, and soil upheaval for sewers, are all the factors yet charged. Perhaps there is some general influence whose laws we do not yet know that should be added to these."

— Dr. C. K. Mills, in the *Polyclinic*, speaking of local hysteria and the difficulty of detecting hysterical deafness, gives the preference for that purpose to the Cammann's binaural stethoscope, used by David Coggin in one medico-legal case, for detecting simulated unilateral deafness, as being as sensible as it is simple. Coggin thus described its use: "The patient affirmed that he was deaf of the left ear. I therefore inserted a tightly fitting wooden plug into the right caoutchouc tube, and then put the two caoutchouc tubes into the metal ones. When I tried the instrument on myself, I found that words spoken could not be understood by the right ear. After the patient had adjusted the stethoscope, he repeated without hesitation the words which I had whispered into the bell of the instrument, which served as a mouth-piece. The tube containing the plug was then taken out of the right ear, which was firmly closed by pressure on the tragus. When I again spoke into the stethoscope, which was still in connection with the left ear, the patient positively assured me that he could no longer distinguish the words. He was, of course, aware that the tube through which he had before heard was no longer in connection with the right ear."

— The Boston Board of Health last week issued new quarantine regulations. Hereafter vessels coming from infected ports, or having on board infected cargoes, are to remain at the quarantine station until released by the port physician, who is given full powers in the matter, and the cargo is to be disinfectant in the storehouse on Galloup's Island, cases of illness being attended to in the hospital there, as before.

— Prof. Henry W. Acland, of Oxford, has been made a Companion of the Order of the Bath.

— Professor Jaccoud has been transferred from the chair of Internal Pathology in the Paris Faculty of Medicine to that of Clinical Medicine made vacant by Professor Laségue's death.

NEW YORK.

— On the 21st of October a reception was given at the Mount Sinai (Jewish) Hospital to afford its friends an opportunity of examining a number of improvements which have been made in the institution during the last eighteen months. Among these have been the erection of eye and ear infirmaries and an isolated building for cases of contagious disease occurring in the hospital. The inner walls of the main building have also been renewed in order to guard against the danger of absorption of infectious matter, and the

¹ Lehrbuch der Psychiatrie.

² Die Manie.

total cost of the improvements is about \$60,000. The institution now contains 168 beds, and two new perpetual beds have recently been founded by wealthy Hebrews.

—The ninth annual meeting of the Board of Relief of the United Hebrew Charities was held October 28th, when the president, Mr. Henry Rice, made a report of the work done by the Board, and recommended, among other suggestions in regard to its future work, that a medical graduate and a trained nurse should be employed to devote their whole time to labor among the outside poor, caring for the sick, inspecting dwellings, and teaching the necessity of cleanliness and ventilation and other laws of hygiene.

—The Board of Managers of the New York Infant Asylum recently obtained a temporary injunction, with an order to show cause why it should not be made permanent, against the Board of Health of the town of East Chester (which had been investigating the condition of the branch of the asylum located at Mount Vernon, West Chester County), restraining them from interfering in the management of the sanitary and medical affairs of the institution. The case was set down for argument before Justice Dykman, at White Plains, on the 29th of October, when the latter rendered a decision to the effect that the injunction should be made permanent, thus denying the right of the Board of Health to interfere. In case of an epidemic, such, possibly, as that of measles and diphtheria, which had been in progress at the asylum, he said, the Board had the power to quarantine the institution so as to prevent the spread of disease, but not to do anything more. If there was any mismanagement in the care of the inmates the Board could act only through an indictment or civil suit.

—Dr. C. Fayette Taylor and his partner, who have a private orthopaedic hospital on a corner of Sixth Avenue where the elevated railway passes on two sides of the institution have won a suit against the Metropolitan and Manhattan Elevated Railroad Companies in the Superior Court, the jury granting them \$20,000 out of the \$25,000 which they claimed. This was the second trial, the jury in the first trial having failed to agree. The plaintiffs sought to recover damages for depreciation of property and injuries to their business, they having leased the property before the road was built, and they claimed that the trains injured their business on account of the dirt, noise, foul gases, and obstruction of light and air consequent upon running them. The defense held that the roads were legally built, and were a public necessity.

—A tramp, who had recently been sleeping in lodging-houses in various parts of the city, having died of typhus fever on the 29th of October, Dr. Jones, the assistant sanitary superintendent, instituted an immediate and rigid inspection of all the places frequented by this class of persons in order to prevent the occurrence of an outbreak of the fever among them.

—One of the passengers of the Cunard steamship *Scythia*, which arrived on the 31st of October, having

been attacked with small-pox during the voyage, the vessel was detained at quarantine until she had been fumigated and all her passengers vaccinated.

—The Hudson County (N. J.) Grand Jury, on making a recent visit of inspection to the Passaic River found that nearly all the main sewers of the city of Newark emptied into the river, and that the tide carried the sewage some distance above the pumping station at Belleville, where the water is pumped into mains by which Jersey City is supplied. It is probable that in consequence of this the Grand Jury will indict the city of Newark for maintaining a nuisance.

—An epidemic of diphtheria broke out in the State Institution for the Blind at Batavia, N. Y., on the 19th of October, and three of the cases have thus far proved fatal. The institution has consequently been closed, and as many of the pupils as possible sent to their homes.

—During the month of October 2567 deaths and 2790 births were reported in New York. The deaths from contagious diseases were as follows: measles, 23; scarlet fever, 32; diphtheria, 78; typhoid fever, 87; typhus fever, 2; and cerebro-spinal meningitis 17.

—Sir William MacCormack, F. R. C. S., has lately been in town, and has been the recipient of considerable attention. On Thursday evening, October 25th, Dr. J. Marion Sims and his son, Dr. H. M. Sims, gave a large and elegant reception in his honor.

Miscellany.

THE MISTAKEN DIAGNOSIS IN THE CASE OF THE COMTE DE CHAMBORD.

M. VULPIAN has published an account of the symptoms in the final illness of the late Comte de Chambord, which explains the uncertainty in the diagnosis and the final adoption of that of cancer which was negatived by the autopsy. *L'Union Médicale* (September 18th) contains a résumé of this article, by which it appears that the symptoms pointing to digestive impairment dated from early in June, soon followed by the detection of an epigastric tumor. Vulpian was called in consultation in July, and after a second examination in presence of all the attendants the following diagnosis was made: Cancer of the stomach *en plaque* at some distance from the pylorus; fatty degeneration of the heart; atheroma of the arteries; slight interstitial nephritis. What determined them toward the diagnosis of cancer was, besides the epigastric tumor, which was deep, large, painful, to the right of the median line, ill-defined, and of the size of the palm of the hand, the fact that ingestion of food caused, after five or ten minutes, pain, with vomiting, the latter also occasionally occurring before breakfast. No blood was ever ejected. The patient's uncle had died of cancer of the stomach.

A milk diet caused an amelioration of the symptoms, so that there was some doubt of the diagnosis, but death occurred August 24th. The autopsy was only partial, being such as could be made incidentally to the process of embalming. The tumor was found to consist of thickened fatty mesentery, with a great number of hypertrophied and inflamed lymphatic ganglions,

non-cancerous. Localized peritonitis, hypostatic congestion of the right lung; heart of the color of a dead leaf, flabby, no valvular lesions, atheromatous patches in the aorta. The principal lesion, which caused the most surprise, was in the lower fifth of the œsophagus; several ulcerations of variable size were found here. They had destroyed all the mucous membrane, and had exposed the muscular coat; edges perpendicularly cut or beveled, some showing evidence of commencing cicatrization; nothing in the upper part of the œsophagus. The stomach showed the appearance of chronic catarrh; near the pylorus were some little ulcerations, only one of which looked like those of the œsophagus. M. Vulpian, while of course admitting the error of diagnosis, considers it excusable under the evidence, and indeed says that with the same signs he should make the same diagnosis again.

THE ELASTIC RESPIRATOR IN THE TREATMENT OF DYSPNŒA IN THE EMPHYSEMATOUS.

PROF. BAZILE FÉRIS, considering the dyspnœa associated with emphysema the most painful and troublesome symptom of the disease, has devised an apparatus which he terms the "elastic respirator". to render breathing deeper and easier. The chief cause of the dyspnœa is loss of elasticity in the alveolar walls, the chest being fixed in the inspiratory position; any therapeutic resource therefore which will facilitate expiration, or restore to the lung its lost elasticity, will abolish the dyspnœa. The apparatus designed by the author is extremely simple and light. It resembles exactly a double hernia truss: from a pad situated between the shoulders, the two limbs of the truss pass round under the arm-pits to the terminal pads in front, which are rather larger and thinner than those of a hernia truss. Light straps passing over the shoulders keep the pads in position. The parts at which these pads should be made to exercise pressure are the least resistant parts of the thoracic wall, usually the upper and anterior part of the chest, over the cartilages and the ends of the ribs. The first effect of the pressure so applied is to drive out the air from the chest, that is, expiration is effected; inspiration then follows without any effort, as the inspiratory muscles are not enfeebled, but have rather increased in volume; then again artificial expiration, and so on. The increased movement by the chest wall so obtained was clearly shown in some tracings taken by M. Constantine Paul.

The actual practical results obtained by M. Férís, in the treatment of thirteen cases of emphysema, were very striking. The relief to the dyspnœa was as a rule instantaneous; patients could walk, go up and down stairs, sometimes even run with little fatigue. One patient was so much improved that he left the hospital without his respirator; he had not gone three hundred yards, however, till he came to a stand-still, and had to return to the wards leaning on the arm of an attendant; then, having put on his respirator again, he went out in comfort, and did not return for seven hours. Four very striking and successful cases are recorded in detail.

The author's account of the benefits derived from using his apparatus is still further confirmed by experiments with the spirometer; it was found that breath-

ing easily with the respirator in position the volume of air respired was nearly double that respired without the apparatus. Another point worthy of notice is that not only does this respirator deepen and facilitate respiration, but it diminishes the rapidity of the respiratory movements. In the aged, in whom the chest wall is more rigid, and in cases where the emphysema is complicated by extensive bronchitis, the relief is less striking than in the opposite conditions. — *Bull. Gén. de Thérap.*, August 15, and *Glasgow Medical Journal*, September, 1883.

TYPHOID FEVER IN CONNECTICUT.

THE Secretary of the Connecticut Board of Health reports for August that "the prevalence of typhoid fever is the most important element in the sanitary history of the month, when the relative prevalence of this type of disease and malarial diseases are considered. A few years ago scarcely a case was reported from the malarial region; now the cases begin to exceed the malarial, and in places like Manchester, where the two types exist together, the influence is seen in the prevalence of typho-malarial fever. Two fatal cases of this form are reported from South Manchester, and several cases of typhoid fever. The use of a small stream for the disposal of sewage, which is obstructed by numerous dams, thus causing beds of deposits, which from the natural effects of the dry season must have been more or less uncovered and exposed to the sun, furnishes favorable conditions for the causation of typho-malarial fever. This has been repeatedly illustrated in different places. These same agencies would favor the spread of typhoid fever were the malarial influence wanting. The general decrease in the prevalence of malaria and the malarial influence upon other diseases is very marked, in a large part of the territory, where they have been for quite a long period the governing type. With a few exceptions, which tend to strengthen the idea that there must be some local causes to induce the unusual prevalence, I cannot learn of any general activity in the progress or spread of malaria. While there is a much greater prevalence and a more marked influence over other diseases in the northeasterly frontiers of the region that has already been invaded by malaria, there is no such decided prevalence as exists in the region about Manchester. As has been stated acute-intermittent is very common, and both typho-malarial and malarial fevers exist. In the present uncertainty as to the ultimate nature of malaria, all such manifestations are of peculiar interest.

"The cases reported from Hampton this month and previously were imported by a gang of Italian laborers. A few cases of typho-malarial are reported in August, also typhoid fever, the latter indigenous.

The prevalence of typhoid fever is noticeable in Waterbury; in New Hartford, Thomaston, and several places in Litchfield County; in a part of Killingly, and in several towns in Windham County. More or less cases of typhoid fever are reported also from different parts of every county.

A SEVENTH SENSE.

SIR WILLIAM THOMSON, the eminent Professor of Mathematics in the University of Glasgow, according

to the *British Medical Journal*, in his inaugural address, delivered last week, as President of the Midland Institute, at Birmingham, broached the idea of the existence of a magnetic sense. This sense he called the seventh sense, to distinguish it from our other six senses—namely, those of sight, hearing, taste, smell, heat, and force. He said that, in speaking of a possible magnetic sense, he in no way supported that wretched, groveling superstition of animal magnetism, spiritualism, mesmerism, or clairvoyance of which they had heard so much. There was no seventh sense of a mystic kind. Clairvoyance, and so on, was the result of bad observation, chiefly, somewhat mixed up with the effects of willful imposture, acting on an innocent and trusting mind. If there were not a distinct magnetic sense, it was a very great wonder that there was not. The study of magnetism was a very recondite subject. One very wonderful discovery that was made in electric magnetism was made by Faraday, and worked out very admirably by Foucault, an excellent French experimenter, showing that a piece of copper, or a piece of silver, let fall between the poles of a magnet, would fall down slowly, as if through mud. Was it conceivable that, if a piece of copper could scarcely move through the air between the poles of an electric magnet, a human being or living creature, in the same position, would experience no effect? Lord Lindsay got an enormous magnet, so large that the head of any person wishing to try the experiment could get well between the poles; and the result of the experiment was marvelous, the marvel being that nothing was perceived. Sir William Thomson, however, was not willing to admit that the investigation was completed. He could not but think that the quality of matter in the air, which produced such a prodigious effect on a piece of metal, could be absolutely without any perceptible effect whatever on a living body. He thought the experiment was worth repeating; and it was worth examining whether or not an exceedingly powerful magnetic force was without perceptible effect on a living vegetable or animal body. His own speculations had led him to conclude that there might be a seventh or magnetic sense; and that it was possible an exceedingly powerful magnetic effect might be produced on living bodies that could not be explained by heat, force, or any other sensation.

CULTURE AND NATURE.

MR. SPENCE BATE, F. R. S., in a recent address called attention to an inverse ratio which he believed to exist between the development of the cranium and that of the teeth. The teeth of Esquimaux, Red Indians, natives of Ashantee, as well as some specimens from primeval man, were shown to be more perfect than most of those from modern Europe, the latter presenting so-called interglobular spaces which are wanting in less civilized races, and in the rare instances of perfect teeth found among highly developed peoples. Not only the dentine, but also the enamel, is said to be deteriorating. In gross appearance, too, as well as histologically, the teeth are changing. Mr. Bate believes that the tendency for the cranium to develop at the expense of the face and lower jaw is marked as we ascend the scale of the vertebrates. As

the jaw atrophies, there is less space for the growth and play of the teeth. It is certainly an apparent fact that in vertebrate evolution the tendency is to the disappearance of teeth. The lower vertebrates are said to have four molars on each side in each jaw, the higher three, while man has but two.

The London *Spectator*, commenting on these facts, says: The facts being granted, the question arises whether these symptoms will end in a decay of the race, or in an extinction of each cultivated class as it springs up, the learned perishing while the barbarians below them flourish. The latter is the more probable, for nature seems opposed to the steady transmission of high brain power. Genius does not breed; and families over cultivated for their physique have long been known to tend either to sterility, to insanity, or to decrepitude. It may be found yet that the hopes of Comte are exactly opposed to the conclusions of science, and that a race, after developing its force, as, for instance, the Chinese did, can only be saved by becoming strictly non-progressive. Humanity may continue only on condition of its healthy barbarians always rising to the top. The professor may rule the costermonger, but the costermonger's progeny will always survive the professor's.

THE NATURAL HISTORY OF DYSMENORRHEA.

DR. JOHN WILLIAMS, of London, has recently written a paper on the above subject, which is reviewed at some length in the *Lancet* (September 15th). We extract the following, which are the author's general conclusions:—

"(1.) Dysmenorrhœa should be studied first under the least complex conditions—in single women. (2.) Dysmenorrhœa in single women is rarely acquired; it is almost invariably primary, namely, it appears with the menstrual function. (3.) Dysmenorrhœa in a few, but rare, cases, ceases spontaneously a few years after puberty. (4.) Marriage, if sterile, aggravates the disorder in many cases; it is only very seldom that it relieves the pain. (5.) Child-bearing cures a large number of cases, and it is not impossible that were all puerperal complications excluded it would cure every case. (6.) The proportion of sterile to fertile women subjects of primary dysmenorrhœa is one to twelve. (7.) Menstruation begins in women who become sufferers from primary dysmenorrhœa at about the estimated average age for the appearance of the function in London. (8.) Menstruation is regular in about two thirds of the cases, and irregular in about one third. (9.) The menstrual fluid is profuse in about two fifths of the cases, scanty in about one half. It contains clots or shreds in about three fourths. (10.) The changes which take place in the fluid in the course of dysmenorrhœa are various, and cannot at present be classified. (11.) The uterus is imperfectly developed. It may be too short, or too small in volume, or it may be defective in both respects. The cervix may be conical and the os small and round, but stricture of the canal in any part of its course is infinitely rare. (12.) The changes in the uterus due to dysmenorrhœa are slight hypertrophy, erosion and eversion of the mu-

cous membrane of the cervix, and catarrh. The cavity increases but little in length, for after years of suffering it measures rarely more than two and a half inches in length. In the early stages the tissues of the uterus are in some cases soft; in the more advanced, hard. (13.) The hypertrophy of the uterus is probably the result of periodically increased muscular action. (14.) Ovaritis and perimetritis are possible consequences of dysmenorrhœa. (15.) The menstrual pain is the result of spasm of the uterus, excited by the separation and expulsion of shreds of decidua and clots, in an organ whose sensitiveness in the performance of its function is enhanced by inappreciable conditions of tissue dependent on imperfect development, often associated with others, such as anæmia."

DIAGNOSTIC VALUE OF UTERINE HEMORRHAGE AFTER THE MENOPAUSE.

DR. T. GAILLARD THOMAS, in a recent clinical lecture on malignant disease of the neck of the womb,¹ stated as an axiom in gynecology, that if a woman who has normally ceased to menstruate begins to have uterine hæmorrhage one should always suspect carcinoma. "Not infrequently you will see in the medical journals the reports of cases where women who have passed the change of life have begun to menstruate regularly again, but such accounts are altogether deceptive, and if these cases could be followed out it would be found, with scarcely a single exception, that the uterine flow was merely the indication of the presence of malignant disease. In other words, there is absolutely no such thing as a return of the menses when a woman has once reached the normal menopause. Not long since a patient of mine in the Woman's Hospital, who is sixty years of age, began to have a flowing from the uterus, and as there was no indication of any external disease I applied the curette to the endometrium, and drew out some pulpy masses, which I sent to a well-known microscopist for examination. The report that I got from him was that the growth was not malignant in any respect, but was simply a form of polypus. I am perfectly sure, however, that the microscopist is wrong, and for this reason, in the uterus of a woman of sixty polypi never develop. The organ at that age is completely atrophied. Sometimes in women who have passed the menopause you will find uterine tumors which have all the appearance of fibroids. They are not by any means fibroids, however, but sarcomata."

THE TREATMENT OF MEASLES.

DR. D. MACLEAN, of Edinburgh, in the *Lancet* (October 13th), after referring to the disastrous results sometimes met with in individual cases of measles, and the fatal epidemics which have occasionally visited communities long exempt, thereby attacking an unusual number of adults, says regarding treatment:—

"As this disease is considered one of the zymotic class we have in its treatment to consider principally two things: (1) the management of the ferment or whatever it is, and (2) the management of the effects

of this ferment upon the system. The most marked of these latter present themselves to us in the effects of the ailment upon the mucous membranes. The greatest action of the disease, as we all know, is upon the mucous membrane of the lungs, and it is from its action there we have the immediate cause of the ensuing death or the prolonged ill health afterwards. We have thus clearly set before us the line of action to follow: (1) to relieve the congestion of the mucous membrane, which is the immediate cause of danger, and (2) to destroy or reduce the violence of the disease itself. This I have been in the habit of doing, I believe successfully, by giving (say to a child of two or three years of age) a teaspoonful in water of the following mixture every three hours: ipecacuanha wine, half a drachm; syrup of squilla, half an ounce; quinine, two grains; acetate of ammonia solution to two ounces. Of course the quinine is increased according to age. We have thus in this mixture a stimulating expectorant and diaphoretic to relieve the tension in the mucous membranes and the skin, and also in the quinine a specific to destroy or abate the violence of the primary ferment. It may be necessary to add to or modify the form in which this plan of treatment is carried out, as when the irritation and cough are persistently great, then the addition of a little tincture of hyoscyamus is all that is necessary. So with the quinine; sometimes the stomach is so irritable that it is necessary to omit it from the mixture; but as it is essential that it be introduced into the system for the destruction of the ferment it can be administered separately by giving it in powder mixed with saccharated carbonate of iron, which diminishes the irritant action of the quinine that takes place when the drug is given alone.

"This form of treatment for measles is good in all types of the disease, whether the attack be mild or severe, and more especially valuable when we have that dangerous form in which the eruption is of a deep-purplish color, a form which is generally recognized as being the most fatal. This style of treatment I have followed for a number of years. I have seen many cases, and, as a justification for submitting it to the notice of the profession, I do not remember having signed a certificate of death for either the disease itself or its effects."

ADMINISTRATION OF QUININE.

THE following summary gives the pith of notes on the administration of quinine contributed by Dr. David Young, of Rome, to the *London Practitioner*:—

(1.) Never to give quinine in antipyretic doses in cases where the bowels are confined and the secretion of urine is scanty.

(2.) In cases where it is being administered and an increase of dose is desirable, this may be safely done if the skin, bowels, and kidneys maintain their normal functional activity.

(3.) In many cases of remittent and intermittent fevers the combination of the drug with chloride of ammonium or a salt of potash or soda is likely to be more easily tolerated, as well as more useful, than if it be administered in a pure form.

(4.) During the administration of quinine should a headache come on or increase in intensity the case requires the most careful attention.

Deaths reported 2412 (no report from Buffalo): under five years of age, 871: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 603, consumption 350, lung diseases 202, diphtheria and croup 196, diarrhoeal diseases 127, typhoid fever 77, scarlet fever 51, malarial fevers 42, whooping-cough 22, cerebro-spinal meningitis 16, measles 12, small-pox eight, puerperal fever eight, erysipelas four. From *scarlet fever*, Philadelphia 10, New York nine, Baltimore seven, Brooklyn and St. Louis six each, Chicago five, Boston four, New Orleans, Pittsburg, Worcester, and New Bedford one each. From *malarial fevers*, New York and New Orleans 11 each, St. Louis eight, Brooklyn five, Baltimore, and New Haven three each, Chicago one. From *whooping-cough*, New York seven, Philadelphia four, Brooklyn, Chicago, New Orleans, and District of Columbia two each, Boston, Cincinnati, and Lynn one each. From *cerebro-spinal meningitis*, New York four, Philadelphia, Chicago, and Cincinnati three each, Lowell two, Providence one. From *measles*, New York eight, Philadelphia, New Orleans, District of Columbia, and Gloucester one each. From *small-pox*, New Orleans six, Philadelphia two. From *puerperal fever*, Philadelphia, Baltimore, Cincinnati, two each, Brooklyn and New Haven one each. From *erysipelas*, New York three, Philadelphia one.

Thirteen cases of small-pox were reported in St. Louis; scarlet fever 52, typhoid fever 27, and diphtheria 25 in Boston; scarlet fever 15, and diphtheria five in Milwaukee.

In 39 cities and towns of Massachusetts, with an estimated population of 1,015,703 (estimated population of the State 1,922,530), the total death-rate for the week was 18.69 against 19.34 and 18.53 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending October 13th, the death-rate was 20.2. Deaths reported 3333: acute diseases of the respiratory organs (London) 248, diarrhoea 171, scarlet fever 116, measles 56, fever 56, whooping-cough 45, diphtheria 32, small-pox (London three, Birmingham and Sunderland two each, Newcastle one) eight. The death-rates ranged from 11.7 in Leicester to 32.3 in Preston; Sheffield 16.3; Birmingham 17.7; Bradford 18.9; London 19; Bristol 19.6; Nottingham 22.8; Liverpool 23.6; Leeds 26; Manchester 27.2. In Edinburgh 17; Glasgow 21.7; Dublin 25.8.

For the week ending October 6th, in 171 German cities and towns, with an estimated population of 8,731,018, the death-rate was 22.9. Deaths reported 3843; under five years of age, 1988; consumption 476, diarrhoeal diseases 296, lung diseases 267, diphtheria and croup 224, scarlet fever 116, typhoid fever 77, whooping-cough 67, measles and röteln 46, puerperal fever 28. The death-rates ranged from 10.8 in Wiesbaden to 33.5 in Halle; Königsberg 32.2; Breslau 31.1; Munich 28.2; Dresden 22.2; Berlin 24.6; Leipzig 17.2; Hamburg 19.3; Cologne 25.2; Frankfurt a. M. 17.8; Strasburg 20.6.

For the week ending October 13th, in the Swiss towns, there were 32 deaths from consumption, diarrhoeal diseases 26, lung diseases 13, whooping-cough 11, typhoid fever seven, small-pox one, scarlet fever one, diphtheria one. The death-rates were, at Geneva 20.5; Zurich 12; Basle 20.6; Berne 20.3.

The meteorological record for the week ending October 27th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

[Date.	Barom-eter.	Thermome-ter.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM OCTOBER 26, 1883, TO NOVEMBER 2, 1883.

MOORE, JOHN, lieutenant-colonel and assistant medical purveyor. To be relieved from duty as medical director, headquarters Department of the Columbia, to proceed to San Francisco, California, and assume charge of the medical purveying depot in that city. Paragraph 10, S. O. 243, A. G. O., October 24, 1883.

McKEE, JAMES C., major and surgeon. Relieved from duty in the Department of California, and assigned to duty as medical director, Department of the Columbia. Paragraph 5, S. O. 249, A. G. O., October 31, 1883.

WOLVERTON, WILLIAM D., major and surgeon. Granted leave of absence for one month. Paragraph 6, S. O. 201, Department of the East, October 24, 1883.

MERRILL, J. C., captain and assistant surgeon. Granted leave of absence for one month. Paragraph 7, S. O. 201, Department of the East, October 24, 1883.

ERRATUM. — In the article in the JOURNAL of November 1st, on Kairin, by Dr. George B. Shattuck, the sentence at the top of page 415, second column, should read: "It is now sold for \$3.75 an ounce, and I believe that the process employed for its preparation may with an increasing demand be so improved as to allow it to be sold at a much cheaper rate, and make it considerably cheaper than quinine."

OBITUARY. — Died, at East Douglas, Mass., October 29, 1883, Alba Enoch Kemp, M. D., M. M. S. S., aged sixty-one years.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for *Clinical Medicine, Pathology, and Hygiene* will meet at 19 Boylston Place, on Wednesday, November 14th, at 7.45 o'clock. The following papers will be presented: Dr. G. H. Lyman, *Tinnitus Aurium and Vertigo as Prominent Symptoms of Lithæmia*. Dr. J. J. Putnam, *Recent Views concerning the Diagnosis and Treatment of Lithæmia*. Drs. S. G. Webber and David Hunt will open the Discussion. Dr. A. F. Holt, *Medical Examiner for Middlesex, Sudden Death by Hæmorrhage from the Hepatic Vein*. Drs. F. A. Harris and F. W. Draper, *Medical Examiners for Suffolk*, will open the discussion.

ALBERT N. BLODGETT, Secretary.

BOOKS AND PAMPHLETS RECEIVED. — Chemistry. Inorganic and Organic. By Charles Loudon Bloxam, Professor of Chemistry in King's College, London. New American, from

the Fifth London, Edition, thoroughly revised and much improved. Philadelphia: Henry C. Lea's Son & Co.

Transactions of the New Hampshire Medical Society at its Ninety-Third Annual Session, held at Concord, June 19 and 20, 1883.

The Treatment of Wounds as based on Evolutionary Laws By C. Pitfield Mitchell, M. R. C. S., etc. New York: J. H. Vail & Co. 1883.

Diagnosis of Ovarian Tumors. Lectures delivered by Edward Borck, A. M., M. D., Professor of Surgery, etc., etc. St. Louis, Mo. 1883.

Delayed and Non-Union of Fractures. By N. Senn, M. D., Milwaukee, Wis. (Reprint from the Weekly Medical Review of September 29, 1883, Chicago and St. Louis, 1883.)

How to be Weatherwise. A New View of our Weather System. By Isaac P. Noyes. Second Edition. New York: Fowler & Wells. 1883.

The Antiseptic Treatment of Typhoid Fever. By G. C. Smythe, A. M., M. D., Professor of Principles and Practice of Medicine, Indianapolis. Read before the Medical Society of the Mississippi Valley, September 19, 1883.

Alcoholic Insanity. By Lewis D. Mason, M. D. (Reprint.)

Cruise of the Revenue Steamer Corwin in Alaska and in the Northwest Arctic Ocean in 1881. Notes and Memoranda, Medical and Anthropological, Botanical, Ornithological. Washington. 1883.

Quarterly Report of Medical Officers, United States Army, with their Stations and Duties, October 1, 1883. Washington: Surgeon-General's Office.

Water Pollution. Wells. By Irving A. Watson, M. D., Secretary New Hampshire State Board of Health. (Reprint.)

An Ethical Symposium. Being a Series of Papers Concerning Medical Ethics and Etiquette from the Medical Stand-point. By Drs. Post, Ely, Vanderpoel, Pilcher, Hun, Wey, etc., etc. With an Appendix. New York: G. P. Putnam's Sons. 1883.

The Climatic Treatment of Pulmonary Consumption. By Charles Denison, M. D., Denver, Colorado. (Reprint.)

Transactions of the New York Medico-Chirurgical Society, 1882. Vol. II.

Divorce in Massachusetts. An Extract from the Forty-First Registration Report. By Frank Wells, M. D.

A Practical Treatise on Materia Medica and Therapeutics. By Roberts Bartholow, M. A., M. D., LL. D., Professor of Materia Medica and General Therapeutics in the Jefferson Medical College of Philadelphia. Fifth Edition, Revised and Enlarged. New York: D. Appleton & Company. 1, 3, and 5 Bond Street. 1884.

The Law of Sex, being an Exposition of the Natural Law by which the Sex of Offspring is controlled in Man and the Lower Animals, and giving the Solution of Various Social Problems. With Forty Illustrative Portraits. By George B. Starkweather, F. R. G. S. London: J. & A. Churchill. 1883.

The Pathology and Treatment of Venereal Diseases. By Freeman W. J. Bumstead, M. D., LL. D., and Robert W. Taylor, A. M., M. D. Fifth Edition. Revised and Rewritten, with many additions, by Dr. Taylor. Philadelphia: Henry C. Lea's Son & Co. 1883.]

Lectures.

ON THE TREATMENT OF DIABETES.¹

A CLINICAL LECTURE BY PROFESSOR DUJARDIN BEAUMETZ.

Member of the Academy of Medicine, Physician to the Hôpital St. Antoine, etc., Paris, France.

GENTLEMEN, — Diabetes² is a very common affection which you will often be called upon to treat when you shall have entered upon your practice; I propose therefore to devote one or two lectures to the therapeutics of this disease. So frequent, in fact, is this complaint, that Bouchardat affirms that out of every twenty men between forty and sixty years of age, and pertaining to the wealthier classes, you are sure to meet with at least one diabetic patient.

Whence comes this really large number of glycosuric patients? It results first of all from the fact that we are better acquainted with the affection, and, moreover, with the conditions of modern life, which in exciting unduly the digestive functions and those of the cerebro-spinal axis, predispose notably to this disease. There is, then, a preponderating interest in knowing the therapeutic rules which ought to be observed in such cases, especially since, when these rules are followed, they cause disappearance of sugar from the urine, and all the troubles which arise from glycosuria. But before entering upon the main part of my subject there are two preliminary questions which must be decided: the pathogeny of diabetes, and the tests which determine the presence of sugar in the urine.

Pathogeny plays an important part in the therapeutics of diabetes; it constitutes aetiological therapeutics, and we cannot discuss scientifically the influence of medicaments and medications till we have examined the mechanism of glycosuria. Thanks to the brilliant researches of Claude Bernard, researches which con-

stitute, perhaps, his best title to glory, we know to-day what is the origin of the sugar which is found in the normal state in the blood of animals.³

This physiological glycæmia has two origins: either it is a fact of alimentation; the feculents and cane sugar being transformed into glucose by the intestinal juice, the salivary diastase, and by the pancreatic juice constitute the first of these sources, or else it is a product of the glycogenic functions of the liver. Claude Bernard has in fact shown us that there exists in the liver an animal amyloid principle, glycogen,⁴ and that this starchy principle under the influence of an hepatic ferment furnishes glucose. Notwithstanding the vehement attacks which Pavy⁵ and Lussana have made upon the doctrine of the normal glycogenic action of the liver, pretending that this sugar formation was simply a pathological or post-mortem phenomenon, the views of Claude Bernard are none the less admitted by the majority of physicians.

Rouget, on his part, generalizing the glycogenic functions, has strongly maintained that all parts of the body, and particularly the muscles, possess glycogenic properties. But we are not obliged to enter into the discussion of all these objections; it suffices us to know that glycosuria, or the passage of sugar in the urine, is the exaggeration of a normal phenomenon, physiological glycæmia, that is to say, the presence of glucose in the blood. The conditions which, exaggerating this physiological glycæmia, transform it into a persistent glycosuria are numerous; and according as they have been exclusively adopted to explain the mechanism of diabetes, a great many theories have been proposed.⁶

³ Claude Bernard has dwelt particularly on the origin of the glucose which is found in the blood. This glycæmia comes from two sources — from alimentation, and from glycogen formed in the liver.

The glucose furnished by food is a product of the digestion of amylaceous matters by saliva and the pancreatic juice, and also of saccharine articles of diet which are transformed from saccharose into glucose by the action of the intestinal juice; this juice contains a ferment which Claude Bernard calls *invertase ferment*. The rôle of the liver in this case is said to be that of a reserve-depot for this alimentary sugar, and to supply it to the blood in proportion as it is required. The glycogen or animal starch (which forms a singular explosive substance with nitric acid, takes a violet color with iodine, and passes to the state of dextrine) in presence of a hepatic ferment is transformed into glucose.

Claude Bernard insists that the formation of sugar in the liver is a normal fact. The liver, then, is the seat of two orders of phenomena — phenomena of assimilation, and phenomena of disassimilation. The first correspond to the formation of glycogen, the latter to its transformation into dextrine and glucose. The more active the life, the more pronounced the phenomena of disassimilation. (Claude Bernard on Diabetes and Glycogenesis, in *Revue des Cours Scientifiques*, 1873.)

⁴ Glycogen is a hydrocarbonaceous substance isomeric with starch; has for formula $C^6H^{10}O_5$; dissolves in water, forming a milky opalescent liquid with, right-handed polarization. Under the influence of dilute mineral acids, saliva, pancreatic juice, blood serum, and of hepatic extract (prepared cold), glycogen is transformed first into a variety of dextrine, then into glucose. This transformation demands for its production a temperature of 30° C. Cold nitric acid transforms it into xyloidin and warm nitric acid into oxalic acid.

⁵ Pavy maintains that the sugar produced by the liver results from a cadaveric transformation, or from pathological conditions. These pathological conditions have their source in the non-fixation by the liver of an excessive quantity of sugar derived from food, and we ought to distinguish here the amylaceous aliments and the azotized aliments. As for the former, we are concerned with the product of an incomplete digestion; as for the latter (the azotized aliments), three conditions may aid their transformation into sugar: (1) general venous stasis, from exaggerated muscular movements, from asphyxia, etc.; (2) troubles in the portal circulation; (3) section of the filaments of the great sympathetic disturbing the hepatic circulation. (Pavy on Diabetes, London, 1862, 1868. Also Lectures in the Lancet.)

⁶ The number of theories put forth as to the cause of diabetes is considerable. As many as fifty have been designated, but all may be referred to five principal theories, which are the following: —

1. The gastro-intestinal theory.

¹ Translated from advance sheets for the Boston Medical and Surgical Journal by E. P. Hurd, M. D., Newburyport, Mass.

² Cantani has given a full history of diabetes, which he divides into four periods: —

The first, which commences with Aretæus and Galen, and during which the presence of sugar in the diabetic urine was unknown.

The second, which commences with Willis, and in which the symptomatology of diabetes was accurately established.

The third, which is associated with the name of Rollo, who, more than any of his predecessors, pursued a practical end while discussing, with more method than they certain theories which were largely adopted.

The fourth, which commences with Claude Bernard, and in which diabetes is studied by the aid of the experimental method from the standpoint of pathogeny and therapeutics at the same time.

Diabetes was known from the most remote antiquity by the physicians of India, where it was described under the name of *sweet urine*, or urine of honey. In two books translated from the Sanskrit diabetes is called *madume'hé*, which means *urine of honey*.

The ancients knew little about diabetes, at the same time Cornelius Celsus mentions it, and Aretæus gave it the name of *diabetes*, from the Greek word *διαβαίνω*, implying that the sweet drinks of persons so affected passed through the body unchanged.

Galen also considered diabetes as a disease of the kidneys attended with elimination of sweet beverages unaltered, and these ideas were adopted by Willis. Moreover, Vittorio Trincavella in support of these Galenic notions cites a case where the urine of a diabetic patient had the same taste as the drinks which he imbibed. During this period Paracelsus alone took a stand against this theory of Galen, and affirmed that the cause of diabetes was in the blood and not in the kidneys.

In 1675 Willis detected sugar, or rather honey, in the urine, and thenceforth the symptoms of this disease came to be better known. Sydenham thought that it was a disease of malassimilation, and Dobson proved by the fermentation test the presence of sugar not only in the urine but in the blood. Lastly, Rollo inaugurated the dietetic treatment of diabetes, which hygienic regime has been crowned by the labors of Bouchardat dating from 1841; and within the present epoch Claude Bernard has given to the world his valuable discoveries concerning glycæmia and the glycogenic functions of the liver. (Cantani on Diabetes. Paris, 1876.)

From the exclusive point of view on which I am placed, that is, the standpoint of treatment, all these theories may be referred to three heads: the hepato-intestinal or alimentary theory; the nervous theory; and, lastly, the theory of nutritive disturbance.

According to the first theory, the glycosuria results either from the too great abundance of saccharine and starchy aliments, or from an excess of activity of the digestive ferments, or from exaggerated action of the functions of the liver. In the normal and physiological state, the glucose which has been formed in the intestinal tube passes into the circulation, and the liver becomes the regulator of this normal glycemia; when the glucose is in too great quantity, it stores it away; when deficient, it furnishes this principle to the economy, thanks to the glycogen which its cells contain. But let some circumstance arise to trouble this harmony,¹ and we pass from the physiological to the pathological state, and glycosuria appears. This glycosuria then entails a series of modifications, more or less grave in the economy, and we soon have all the symptoms of the confirmed disease. This theory is one of the most seductive, and has for its consequence therapeutic applications which dominate in the treatment of diabetes. I refer to the alimentary regime. My venerated master, Bouchardat, has won the claim to public gratitude by founding on this theory that admirable hygienic treatment which enables us through its rigorous application alone to cause the sugar to disappear from the urine of diabetic patients, at least in the great majority of cases; and when this hygienic treatment fails, be assured that the disease will almost invariably resist all other therapeutic means.

The nervous theory is also based on experimentation,² on clinical experience, and on the results of

II. The hepatic theory.

III. The nervous theory.

IV. Theory based on disturbance of nutrition.

V. Pancreatic theory.

I. *The Gastro-intestinal Theory.* This is the theory of Bouchardat. It is divided into two parts—the alimentary theory, and the digestive theory. In the first the sugar of diabetic patients comes from a dietary overcharged with feculent and saccharine matters. In the second the habitual action of the ferments of the digestive tube is too energetic.

II. *Hepatic Theory.* This theory is supported by Claude Bernard. The cause of diabetes consists in a circulatory trouble, in a secretory trouble, or in a simple exaggeration of the function of the liver. It is supported by clinical observations in which diabetes has been observed to arise from hepatic derangements, such as congestions, or even cirrhosis.

III. *The Nervous Theory.* This theory is based on physiological, anatomical, etiological phenomena. Patho-anatomical observations have found in diabetic patients lesions of the floor of the fourth ventricle, congestion, ramollissement, sclerosis of the spinal cord and of the brain, alterations more or less profound of the great sympathetic. From an etiological standpoint, contusions of the encephalon and excesses in the functioning of the nervous system have produced diabetes.

IV. *Theory of Nutritive Troubles.* This is the theory which has recently received the support of Bouchardat. The glycemia of diabetes depends on a fault in the consumption of sugar by the tissues due to a diminution of their nutritive activity. The cause of this retardation is a vicious habit congenital or acquired. Gout and a sedentary life are the most important factors in diabetes. Jaccoud also admits that the cause of this disease is an alteration of nutrition, over production, or lessened destruction of sugar.

V. *Pancreatic Theory.* This theory is based exclusively on pathological anatomy, Lancereaux is its chief supporter. Diabetes is due to lesions of the pancreas, such as atrophy, fatty degeneration, cancer, obliteration of the pancreatic duct.

¹ Colrat and Couturier, taking as their basis certain experiments of Claude Bernard, who showed that when the portal vein is tied the glucose passes directly into the blood, and produces an alimentary glycosuria, have noted that in animals affected with total or partial obstruction of the portal vein from any cause whatever glycosuria always exists.

² Claude Bernard showed, in 1849, that pricking or puncture of the fourth ventricle below the origin of the vagi causes glycosuria.

therapeutics. We know, in fact, since the celebrated experimentation of Claude Bernard, that we can in animals cause a temporary glycosuria by irritating or wounding the rachidian bulb.

Schiff, by traumatic lesions of the entire cerebro-spinal axis, and even of the sciatic nerve, Pavy, Eckhard, Cyon, Aladoff, by traumatism of the ganglia and filaments of the great sympathetic, have arrived at the same result, and have in this way determined a glycosuria equally transient.

I insist on the word *transient*, for it shows us that, unable to produce true diabetes in animals, we cannot practice on this disease experimental therapeutics, for the glycosuria which results from our experiments gets well of itself in the course of several days.

In support of the nervous theory of diabetes clinical medicine furnishes a great number of observations where we see violent blows on the head, or great cerebral excitation, the consequence of too prolonged intellectual labors, painful emotions, chagrin, and disappointment, become the starting-point of diabetes. This it is which explains why this disease is so common among certain classes of the population, such as literary men and persons devoted to scientific and academic pursuits. You will not, then, be astonished to see a considerable number of authorities claiming that diabetes is always of nervous origin.

As for that theory which refers diabetes to disorders of nutrition, it has been quite recently defended, and with considerable success, by Professor Bouchard,³ who has classed diabetes with affections due to retardation of nutrition. Here also we can deduce facts in support of this theory from physiological and clinical experimentation. The glycogenic function is not, in fact, exclusively a function of the liver; all the tissues participate in it. Have we not seen Rouget demonstrate this power of sugar production in all organs of the fœtus? Have we not seen Schiele detect glycogen in stratified pavement epithelium? In fine, do not the muscles themselves participate in this glycogenic function, as Boehm⁴ has pointed out? We can, then, say

Section of the splanchnics after the puncture does not modify the glycosuria, but it prevents it when made before the puncture.

Schiff produced glycosuria by section of the optic thalami, crura cerebri, pons, middle and posterior peduncles of the cerebellum, also by section of the spinal cord on a level with the second dorsal vertebra, by extensive lesions of the anterior and posterior columns, and even by section of the great sciatic nerve. Richter has shown that lesions of the sympathetic have the same effect. Pavy, that section of the superior cervical ganglion occasions glycosuria. Eckhard, Cyon, and Aladoff have attained similar results with sections of the inferior cervical and superior thoracic ganglia. (Schiff, Jour. d'Anat. et de Physiol., 1866. Cl. Bernard, Arch. gen. de Med., 1849. Bouchard, Maladies par Ralentissement de la Nutrition, Paris, 1882.)

³ Bouchard shows the difference which exists between arterial and venous blood *à propos* of sugar. In animals this is 40 centigrammes, that is, one kilogramme of arterial blood in becoming venous blood loses 40 centigrammes of sugar. When you take into consideration the total quantity of blood which is transformed into venous blood it is susceptible of demonstration that a man loses in a day at the least 1850 grammes of sugar; now one gramme of sugar demands for conversion into water and carbonic acid 173 grammes of oxygen, and as a man in health never consumes more than 850 grammes of oxygen a day, this oxygen is incapable of burning all the sugar; there remains then 1000 grammes of sugar which is not consumed by oxygen, but which is destroyed by molecular metamorphoses of the entire organism. So, according to Bouchard, the conditions which give rise to hyperglycemia may be referred to the following heads: (1) everything which prevents the sugar and starch of food ingested from fixing itself in the liver in the state of glycogen; (2) everything which increases the formation of sugar in the liver; (3) everything which interferes with the destructive metamorphosis of sugar in the economy or its fixation in the tissues. (Bouchard, Maladies par Ralentissement de la Nutrition. Paris, 1882.)

⁴ According to Boehm the muscles behave with regard to glycogen like the liver, that is to say, that glycogen augments in the muscular tissue after meals, and is destroyed in muscular work.

with Bouchardat, Jaccoud, and Bouchard that every circumstance which troubles the most processes of assimilation and of dissimilation of all the tissues may be a cause of diabetes.

One other consequence of this theory is to call attention to the elimination of urea in diabetic patients, and to cause this azoturia to play a preponderant part as Lecorche has done.

Ought we to take sides with one or the other of these theories, and base exclusively on any one of them our therapeutic endeavors? By no means; and we ought instead to draw from them all the elements of our treatment. But I must before approaching this main subject of my lecture set forth the clinical means which you ought to make use of in order to determine the presence of sugar in the urine, and the quantity of this abnormal ingredient.

You should, in fact, be aware that we cannot judge of the effects of our treatment but by a daily examination of the urine; our prognosis, moreover, is based on such examination; you should then perfectly understand the modes of testing urine for glucose.

Glycosuric urine is generally abundant in quantity, of a high density, which sometimes attains even 1050; it is frothy, stains the clothing, and has the curious property of attracting flies.

To detect glucose in the urine we avail ourselves of the curious oxidizing and reducing property of this substance in presence of alkaline agents, and without stopping to consider the numerous processes which have been proposed by Krause, Luton, Muller, Maumené, Neubauer, and Vogel, I will mention only those of Heller, Boettger, and Trommer.

The first of these processes is based on the oxidation of glucose by potassa, which by heat generates glucic and melassic acids which give to the liquid under examination a more or less black color according to the quantity of sugar in solution. Bouchardat has substituted for the potassa a chemical which is much more easily obtainable, slaked lime or milk of lime. This test, which is a good one when the urine has a large amount of sugar, loses its value when the quantity of glucose is small; then there is liability to several sources of error; the coloring matter of the urine, for instance, may turn brown under the agency of alkalies. Moreover, albumen and mucus may give a dark discoloration, and even an impure preparation of potassa may give the same color.

The process of Boettger is altogether different; it consists in heating urine supposed to contain glucose with a mixture of subnitrate of bismuth and carbonate of soda; in this white liquid thus formed there is soon seen a black precipitate of oxide of bismuth.¹ Although this test has been modified by my master, Behier, and more recently by Primavera, it is subject to numerous fallacies, and the reduction of bismuth may be accomplished by substances other than glucose. Atfield affirms that almost any kind of urine will effect the reduction of bismuth. Therefore this test is

inferior to those which have for basis the cupro-alkaline liquors.

Trommer was the first to recommend testing for sugar in urine by utilizing the reducing properties of glucose on salts of copper, and it is upon this basis that a number of test liquids have been devised, Barreswil's and Fehling's solutions for instance.²

Fehling's solution is the most used at the present day; the reaction is very pronounced, and it suffices to heat in a test tube a mixture of glycosuric urine with one of those cupro-alkaline solutions to see the liquid change from a beautiful blue to a pale yellow, then a lively red, in consequence of the precipitation of the oxide of copper, which gradually settles down to the lower part of the test tube.

At the same time with this method, which is much the most certain, all chances of error are not avoided. Uric acid, urinary pigment, tyrosin, may cause the precipitation of oxide of copper, but this precipitation is much less clear and pronounced than that with glucose. Moreover, albumen prevents this reaction from taking place, therefore it will be necessary to have care when you are examining urine that contains both albumen and sugar (which frequently happens) first to precipitate and filter out the albumen before proceeding to test for sugar.

The employment of the cupro-sodic liquors enables us not only to recognize the presence of sugar, but also to determine the quantity, and this is a matter of great importance. I shall not here speak of the polarimetric processes while admitting that they are the most sure and precise, and that one ought always to have recourse to them when desirous of attaining mathematical exactness in the dosage of glucose, but these are methods of the laboratory, and few physicians can have at their disposal a saccharimeter, whether it be that of Soleil, or the one with a *penumbra*, or the diabetometer of Yvon. I shall only mention the clinical processes which are quite sufficient in practice.

Of all the clinical processes the most simple, the most ready, and the most economical is that of Duhomme,³ which we use every day in the hospital and in private practice, and every physician, it might almost be said every diabetic patient, ought to have one of these little instruments for measuring the amount of sugar in the urine.

It is composed of a little box which has in its interior some test tubes, a spirit lamp, two vials, the one containing a little liquor sodæ, the other Fehling's so-

² There are several formulæ for cupro-potassic or cupro-sodic solutions. These are the principal:—

SOLUTION OF BARRESWIL.

R. Carbonate of soda	40 grammes.
Cream of tartar	50 grammes.
Caustic potash	40 grammes.
Water	400 grammes. M.
Add. Sulphate of copper	80 grammes.
Water	250 grammes. M.

FEHLING'S SOLUTION.

Take of pure Sulphate of copper	40 grammes.
Distilled water	160 grammes.
Caustic soda	130 grammes.
Neutral tartrate of potas.	160 grammes.
Distilled water	600 grammes. M.

Trommer's test, the first in use, is employed as follows: Take a sufficient quantity of liquor potassæ and a solution of sulphate of copper. Into a certain amount of urine in a test tube add an equal quantity of liquor potassæ and two or three drops of the solution of cupric sulphate. If the urine contains sugar the blue mixture with hydrate of copper clears up by agitation, and if the tube is heated a precipitate of reddish cupric oxide is formed.

³ Duhomme, Clinical Saccharimetry, Bull. de Ther., t. lxxxviii., 1875, pp. 163, 214, and 261.

¹ [Boettger's test, which is much in use in this country, is practiced in the following manner: A few cubic centimetres of the urine are mixed in a test tube with an equal volume of solution of sodium carbonate (one part crystallized carbonate and three parts water) a few granules of bismuth subnitrate are added, and the mixture boiled for some time. If sugar be present the bismuth turns brown or black by reduction to elementary bismuth. (Witt-haus' General Medical Chemistry.) Witthaus affirms that no other normal constituent of the urine reacts with this test, but there may be some substance present which, by giving up sulphur, may cause the formation of a black bismuth sulphide. — TRANS.]

TABLE GIVING THE RESULTS OF THE RAPID ANALYSIS OF SUGAR BY THE METHOD OF DUHOMME WITH THE GRADUATED DROPPING TUBE OF LIMOUSIN.

Number of Drops contained in one Cubic Centimetre of Urine Examined.		Number of Drops Employed.

Figures indicating in grammes the quantity of sugar contained in each litre.

Figures indicating in grammes the quantity of sugar contained in each litre.

EXPLANATION. — The figures in the first horizontal line correspond to the number of drops employed. The Roman numerals of the first vertical column correspond to the number of drops in a cubic centimetre of the urine under examination. The table reads like the table of Pythagoras. For example, suppose that the urine which you are examining gives 22 drops to the cubic centimetre, and 11 drops are required to decolorise the cupro-sodic solution, you take the figure 11 in the first horizontal line, corresponding to the number of drops employed, and you glance down the vertical column till you come to the point of intersection of the horizontal line which begins with the Roman numeral XXII., and you find the number 20, which indicates that the urine you are testing contains 20 grammes of glucose per litre.

lution, and, finally, two dropping tubes.¹ These two dropping tubes are graduated, the one which is reserved for urine by a mark which indicates a cubic centimetre, the other, which is destined to contain Fehling's solution, by a mark which measures just two cubic centimetres. You begin by taking up one cubic centimetre of urine of which you take care first to count the number of drops by pressure on the rubber ball. Then with the other dropper you aspirate two cubic centimetres of Fehling's solution. This you place in a test tube, and add the same quantity of solution of soda. You then heat the mixture, and after having taken up some of the urine of which you have just counted the drops, you let it fall, drop after drop, into your test liquid, heating the latter from time to time till the entire mixture takes on a reddish color. You have counted the number of drops necessary to obtain this reaction, and you have only to refer to the table herewith given (see adjoining column) to know the quantity of sugar contained in a litre of the urine. This table contains in one column the number of drops present in one cubic centimetre of urine, and in another the number of drops made use of in order to get the characteristic color.

As this method of analysis is very rapid it is desirable, before taking a definite figure, to repeat the process three or four times in order to know exactly the number of drops necessary to obtain the red color in the mixture.

It may be necessary when the percentage of sugar is very large to dilute the urine with an equal quantity of water, which you can easily do by means of your dropper, and in estimating the result you have simply to double the figure obtained. Duhomme has, moreover, given a method for utilizing his saccharimeter for the detection of very feeble quantities of sugar. It suffices in these cases to employ only one cubic centimetre of Fehling's solution, and to count the number of drops necessary to effect the disappearance of the green color you can make use of the same table, but you must move the decimal point one line toward the left.

With this analytical process you can sufficiently estimate the effects of your treatment. You will also have a basis for your prognosis. You are aware that there are two kinds of diabetes. The one is the mild form, *diabetes benignus*, the diabetes of fat people, an affection which permits a person to live a good many years. The other is grave diabetes, the diabetes of lean people, which disturbs profoundly the nutrition of the individual, and determines in quite a short space of time cutaneous, pulmonary, or other complications which rapidly prove fatal.

There has been much discussion as to whether we ought to give the name diabetes to both these affections, some maintaining that the diabetes of the corpulent is nothing but a symptomatic glycosuria, and reserving the name diabetes to the more malignant disorder of lean people; others hold that the two affections are the same, but of different degrees of intensity.

Without entering into this discussion I can affirm that from a therapeutic point of view the examination of the urine will enable you to class your patients in

¹ The dropping tubes graduated to indicate cubic centimetres can easily be obtained of instrument makers.
The method of Duhomme is so handy and simple that it ought to come into general use; it is, in fact, in general use on the Continent. Besides the dropping tubes and the printed table all that is required is the ordinary cupro-sodic testing solutions.

three principal groups: the light forms of diabetes, those of medium intensity, the grave forms. Note first of all that the quantity of sugar which you find is no criterion for prognosis; you may find as much as one hundred grammes per litre, and at the same time have a very mild case. A much more important indication is the persistence of a certain quantity of sugar in the urine in spite of the most rigid dietetic régime.

When, after having made your patient follow scrupulously a rigorous alimentary regimen, you discover that the figure of sugar in the urine keeps at from thirty to fifty grammes per litre, be persuaded that your case is a grave one, and that your pharmaceutical measures, however judicious and appropriate, will not stay the progressive decadence of the organism and the death of your patient. Generally these patients are thin, debilitated, presenting pulmonary complications of a tuberculous nature, and their forces are rapidly exhausted. I have often been called during my medical career to treat such diabetic patients, and despite all my endeavors have not been able for an instant to interrupt the steady decline of the organism.

When, on the other hand, the quantity of sugar, owing to your alimentary hygiene, has fallen to nine or ten grammes a day, you have a case of diabetes of medium intensity. These are the patients who may live many years, but in whom there supervene, when the digestive functions become enfeebled, pulmonary complications, a peculiar comatose state, or it may be cerebral ramollissement, an accident so frequent in those whom Bouchardat calls *petits diabétiques* (that is, persons slightly diabetic). These diabetic patients are amenable to a treatment which opposes to a certain extent the production of such accidents.

In the third group are cases of diabetes of feeble intensity. Here we witness the triumph of alimentary hygiene, for it alone effects very rapidly and in a few days the disappearance of the glucose from the urine, however great the previous quantity. How often have I seen such obese patients, generally arthritic and gouty, who had been voiding two hundred to three hundred grammes of sugar per day, and in whom the régime of Bouchardat has enabled us in a few days to bring down the figure to zero. Nevertheless in these patients the sugar reappears whenever they commit errors in diet.

You see, then, that this dosage of sugar, or, in other words, the determination of the quantity of sugar in urine, is a matter of capital importance to your patients both from the point of view of therapeutics and of prognosis, and I pass now to the consideration of the hygienic and medicinal means applicable to the treatment of diabetes.

(To be continued.)

— A statue of Pinel, the noted benefactor of the insane, is to be erected in the Place de la Salpêtrière, in Paris. The movement was originated by the Medico-Psychological Society, and the project was aided by the Minister of Fine Arts and the municipal council of Paris. The work is by Durand, and comprises two figures, Pinel holding in his right hand broken fetters, and at his feet a young insane girl raising her eyes to her liberator, but with her arms preserving the attitude of being bound.

Original Articles.

A CASE OF DELAYED PUTREFACTION.¹

BY W. H. TAYLOR, M. D., MEDICAL EXAMINER.

ON Wednesday, May 2, 1883, I was requested by the district attorney to make an autopsy upon the body of M. B. A., a woman who was supposed to have come to her death by the administration and effects of poison. Briefly, the history was that she was subject to attacks of hysteria at times, particularly after overwork, and was accustomed to take fluid extract of skull-cap to relieve her "nervousness." Having such an attack about two weeks before her death, after a hard day's work, she took from her husband two thirds of a teaspoonful of a new bottle of skull-cap procured at a reliable druggist's in New Bedford. Shortly after the dose she had a convulsion, and an hour subsequently a second convulsion. She had no convulsions after this, but gradually grew worse, and died on March 24th without remarkable symptoms supervening. Her attendants were of the homœopathic persuasion, and I am unable to obtain a coherent history from them. The consulting physician made some vague remarks about "trouble with the pneumogastric," from which I inferred that the respiration showed some abnormal qualities. He was, moreover, strongly of the opinion that the deceased had been poisoned, and named gelsemium as the agent employed. She had no marked dyspnoea, no marked pulse change, no vomiting, pain, or diarrhoea, and passed a good quantity of urine in which no albumen had been discovered. The information derived from the attendants was sufficiently vague and inconclusive.

The husband of the deceased had never abused his wife, but had been on terms of intimacy with a woman living in the house. Nothing absolutely criminal had been seen, but on sundry occasions he had manifested a degree of affection for the lady's person which seemed ill-adapted to his position as a married man.

The body lay in the house from the 24th to the 27th of March, and was then buried in a church-yard at the top of a high hill; consequently, at the time of my examination, it had been exposed to the influences of decay for forty days.

Owing to the notoriety of the case in the neighborhood, it was deemed best by the legal officers to conduct the examination by night, though I objected on the score of artificial light.

Arriving at the church-yard at nine o'clock P. M., the body was exhumed and carried to a tomb in the vicinity. I noticed that the soil was dry, and a gravelly loam. The body was buried at a depth of five feet for the lowest point. The coffin was an ordinary wooden one, rosewood stained. The body being removed from the coffin, a feeble petroleum lantern was offered as my sole light, and the autopsy was commenced.

The body, which was that of a well-nourished woman of forty-two years, exhibited rigidity, strongly marked. The face was fresh in color, and the eyes were moderately sunken. After removal of the clothing the abdominal walls gave a sound on percussion like a frozen body, and I remarked to the assistants that the body was frozen. An instant's reflection showed this to be impossible, as the ground at that level had been free from frost for a month. The entire in-

¹ Read before the Massachusetts Medico-Legal Society, October 3, 1883.

tegument presented a hard, tallowy feel, indenting on firm pressure, the indentations remaining, with no tendency to a return of the normal appearance. There were absolutely no indications of putrefaction to be seen externally, beyond the slight sunken appearance of the eyes above mentioned. The skin of the abdomen was as white and clear as in life, and the same remark would apply to the entire anterior aspect of the body. The back and the posterior aspect of the arms, forearms, thighs, legs, and neck were of a bright red color, entirely different from the usual post-mortem staining, and this color extended half way up the lateral aspect of the body and limbs. The color was not that of a part reddened by inflammation, but a *bright red*, which perhaps would be described best by the word *brilliant*.

On making the usual median incision, the feel was that of cutting through soap or tallow; the margins of the cut had to be forcibly separated, and would then remain in the position placed without being influenced by gravity. The parts which seemed chiefly concerned in this abnormal state of affairs were the subcutaneous, fatty, and cellular tissue.

The abdominal cavity was perfectly dry. The omental fat presented the same characteristics as the subcutaneous. The viscera were as fresh as if the subject had died within a few hours; even the spleen was hard and firm. The liver was of normal size; its cut surface showed points of central congestion, with slight fatty change in the immediately adjacent cells. The kidneys exhibited a possibly slight diminution in the cortical substance, but there were no marked changes; their capsules were easily separable. The uterus and appendages, bladder and rectum, presented nothing noteworthy. The stomach contained an ounce of stained mucus; it was healthy as to its coats. The intestines were nearly empty; there was a small collection of ordinary-looking fecal matter in the *caput coli* and for a few inches beyond.

The pleural cavities were nearly dry. The lungs were fresh, somewhat congested posteriorly, otherwise normal. The heart was collapsed and dry, about one fifth enlarged; its walls were flabby, and the muscular fibres were somewhat fatty under the microscope. The interior of the cavities was stained black by recent blood-clot, but no old clot was found. No conveniences were at hand for testing the valves, but they appeared normal.

The brain was slightly softened, but could be easily demonstrated; no abnormal appearances were found.

The spinal cord presented the same characteristics as the brain. It was somewhat stained by blood externally, probably from the position it sustained for so long a time after death.

The stomach, intestines, kidneys, a portion of the liver and the spleen were taken, on the following day, to Boston, and examined for organic and inorganic poisons by Dr. Charles Harrington, who reported negatively as to both.

No odor of decomposition was evident about the body either before or after section. An odor was perceptible, but it was an animal odor, which resembled, but was not quite, a *urinous* smell. The fact that it was not disagreeable may be inferred when I state that owing to the state of alarm which the grave-diggers were in we could procure no water to wash our hands, and were obliged to ride fourteen miles home before we could remove the traces of the autopsy; during this time we noticed nothing of an odor

worthy of remark. Coffins in the tomb where the autopsy was made contained three bodies, which had been there for periods varying from three weeks to three months, but there was no odor from these, and they appeared but little changed about the face.

The grave-digger stated that cases of adipoceros change were commonly found when bodies were removed from the church-yard after long periods of interment. Whether the influences which produced this change could have operated to preserve the subject of this paper or not is a matter, of course, beyond demonstration. The observation is noted for what it is worth.

Perhaps no question comes up more frequently and is of more importance to the ends of justice as well as to the interests of a wrongfully-accused person as that of the length of time which has elapsed since death. Data are numerous showing the extreme rapidity with which decomposition supervenes, but little can be found on the retardation of the putrefactive process beyond a few days. With a case of the character of the one reported here in mind, statements relating to the length of time which has elapsed since death, based upon the appearance of the body, would, perhaps, be less positive than has been hitherto too often the custom. When it is considered, in reviewing the case, that the body lay in an inhabited house for three days before burial, in cool, moist weather, without ice or any preservative thrown into the cavities (as I am informed by the undertaker), was subsequently encased in a thin board coffin and buried in loose, gravelly loam, free from frost, where it remained for thirty-seven days before exhumation, and then appeared fresh, with no color or odor of decomposition about it, I think it will be found sufficiently noteworthy to merit the attention of persons interested in forensic medicine.

REPORT ON RECENT PROGRESS IN THE CONSTRUCTION OF INSANE HOSPITALS AND MANAGEMENT OF THE INSANE.

BY WALTER CHANNING, M. D.

PROVISION FOR EPILEPTICS.

UNDER the title *Die Fürsorge für die Epileptischen*, Dr. Pelman continued the discussion of this important subject (which has lately been gone into by Dr. Jolly) at the recent annual meeting of the German Alienists. It will be remembered that Dr. Jolly divides epileptics into four groups, namely: (1.) Epileptics who do not need hospital care, but need public care and can be treated in the out-patient department of general hospitals. (2.) Cases with temporary cerebral disturbance, which must be sent to institutions. This group comprises, (a) cases with transitory mental disturbance, which should go to lunatic asylums; (b) cases temporarily unable to work for their living, which should be in a special section in a general hospital. (3.) Cases that need hospital treatment for a long time, or permanently. To this group belong the chronic insane epileptics, who should go to insane asylums. Others of this group, as paupers, or persons unable to work, would have to go to special institutions. (4.) Epileptic children. These should not be placed with adult epileptics, as such association is injurious. They could be cared for in special wards of idiot asylums.

¹ Allgemeine Zeitschrift f. Psychiatrie, Band xxxix., Heft 5.

There is much uncertainty as to the actual number of epileptics in Germany. Dr. Pelman states that it ranges somewhere from one to six in 1000 of the inhabitants. Dr. Jolly gives only .09 in 1000, which is too small a number. Dr. Pelman gives 1.05 to 1000 as about the correct estimate. In the whole of Germany there are about 45,000,000 persons and 67,500 epileptics. One tenth of these, or from 6000 to 7000 epileptics, will need hospital accommodation.

Only about twenty per cent. of this number will recover. The remaining eighty per cent. will be permanent residents of hospitals. Dr. Pelman does not believe in small institutions for this large number of epileptics, but rather in colonies. He sums up his opinion in the following conclusions: (1.) Insane epileptics, presenting both acute and chronic forms of insanity, should go to insane asylums. (2.) Epileptics who are not insane, but are unable to earn a livelihood, should be brought together into colonies, of a rural character, and in these they should be furnished with out-door employment. (3.) Juvenile epileptics should be placed in institutions similar to idiot asylums, but not connected with them. (4.) Private benevolence should found the epileptic colonies. It might be of a religious character. The State would only give it support in maintaining its position. (5.) Epileptics not needing constant hospital care should receive polyclinic treatment, and occasionally, when necessary, be taken into the special sections reserved for their treatment in general hospitals.

In the discussion which followed the paper of Dr. Pelman, Binswanger said that his experience at the Charité in Berlin has shown him that it was extremely difficult to discriminate between sane and insane epileptics. Sometimes an epileptic would be admitted for insanity, sometimes for epilepsy. Epileptics are often weak-minded, and very easily may have temporary attacks of acute insanity. Dr. Mendel was of the opinion that about ninety per cent. of persons who had had epilepsy for some time were the subjects of some form of mental disease, and Group 2 of Dr. Pelman would comprise but a small number unless he should say "quiet" as well as "persons unable to earn a livelihood." Dr. Pelman agreed with Dr. Mendel that a very large proportion of epileptics showed some mental change, though not as many as ninety per cent., but practically he would not extend his meaning of insane epileptics to an unnecessary degree. Dr. Kind stated that at Bielefeld there was a division for juvenile and idiotic epileptics. He had come to the conclusion that it was not necessary to separate epileptics from other idiots. If they were treated together they were better cared for. Von Gudden agreed with Kind in this conclusion, but said there were often juvenile epileptics not lacking in intelligence, and they should not be put in idiot asylums, but required special institutions. He would ask Pelman if he advised special wards for epileptics in ordinary insane hospitals. The number of epileptics in the asylum with which he was connected was only fifteen out of a total population of 650. This number included both men and women, and they were scattered throughout the various hospital wards according to their mental condition. It would be peculiarly, administratively, and medically difficult to provide separate wards for them. Conclusion 4 did not seem to him absolutely necessary. A good deal was being done to bring religious orders into institutions.

Dr. Pelman said that Jolly made a particular point of *State care* for epileptics, while he made a particular point of *private benevolence*.

THE CARE OF INSANE CRIMINALS.

It will be remembered that this subject, which every year is referred to in so many insane hospital reports, was last year briefly reviewed in this report with special reference to the discussion of the French Society of Alienists. It has been again brought up at the annual meeting of the German Alienists in September last, when Dr. Zinn, of Eberwalde, read a paper entitled *Care of Criminal Insane Persons, or Criminals Suspected of Insanity, etc.*¹

This paper is a very full one, going into the care of insane criminals in England, France, Italy, and America, and comparing the systems of these countries with that of Germany. Dr. Zinn comes to the following conclusions: (1.) Insane criminals admitted into ordinary insane asylums should have no other treatment or surroundings than those in use for the dangerous class of common insane patients. It is the duty of the insane asylum directors to preserve its character as a hospital for the sick, and in no way to change any portion of it to suit the needs of any other class. (2.) A knowledge of psychiatry as well as experience in its practical application are indispensable to the prison physician. (3.) Very acute or rapid attacks of insanity in convicts should be treated in the prison. If the proper arrangements are wanting, they should be made at once. (4.) It is desirable to build prisons for convicts with bodily and mental disease similar to the English invalid prisons. With such buildings, or invalid prisons, all the arrangements necessary for a department for the insane should be combined. Persons belonging to the criminal class, if becoming insane when at liberty or when awaiting trial, should be sent to the insane department of the invalid prison, and detained there as long as there was any possibility of danger to society from them. (5.) Persons who have committed crimes when insane should be sent to an ordinary insane institution. To confine them in an institution for the insane of the criminal class is not right. (6.) Persons during trial, whose mental condition is uncertain, should, if not belonging to the criminal class or not violent or dangerous, be sent to an ordinary insane asylum for observation.

In the discussion following this admirable paper of Dr. Zinn, Dr. Gutsch said that his experience was in accord with that of Dr. Knecht. He did not favor insane departments annexed to prisons, for the physician in charge did not have the independence in the direction that was necessary to successful psychiatric management. He would recommend separate penal institutions (*strafanshalten*), which would provide for criminals with fully developed insanity, as well as those with simple mental defect. With these institutions he would combine hospitals that should possess all the means of treatment for the ordinary insane, and in these could be placed the curable cases, and such as required the particular treatment furnished only in a lunatic asylum.

Von Gudden, Hitzig, Fürstner, and others, expressed themselves as fully in accord with Zinn. Resolutions offered by Dr. Zinn were unanimously adopted, calling on the government to consider the need of providing

¹ All. Zeitschrift f. Psychiatrie, Band xxxix., Heft 5.

for insane criminals, and suggesting the proper rules of action to guide them in so doing.

OCCUPATION OF THE INSANE.

Under the title of Farm-work for the Insane,¹ Dr. Schroeter, of the Dalldorf Asylum, Germany, considers this subject. The employment of the insane as farm-laborers has for many years been believed in by insane asylum physicians, but has only been found practicable within a very recent period of time. Laehr has stated that in the time of Danerow it was sometimes the practice to send insane inmates of institutions out to work for neighboring farmers.

At the present time the labor question is looked at in two ways. Persons on the one side recognize the advantages of employment in the open air for the insane, but, at the same time, advise caution in the choice of the kind of work, and number of cases who are fitted to undertake it, because of the danger of accidents, escapes, etc., and the small number of competent attendants to oversee such work. Those on the other side believe in employment for nearly all of the insane — in recent cases as well as in cases of long standing, and they also believe that most of the insane can undertake ordinary employments, and, with the exception of a small number, live after the fashion of common working people.

In order to give the question fair consideration, and arrive at some definite result, each institution should give employment to as large a number as possible, and publish the results. This has been done in the asylum at Dalldorf since its opening in February, 1880. The insane department contains about 270 men; and it is with these that the experiment has been made. The admissions of men to the insane department are large, 295 having been admitted in the year 1881. Most of these come to the asylum without history, or history of a very brief character. It is therefore necessary to observe them for a short time after admission, though in a certain number of cases, where the disease is of a harmless nature, it may be possible to give them outdoor labor at once. But many who are subject to hallucinations, or are epileptics, or whose insanity has arisen from the use of alcohol, are liable to sudden attacks of excitement, and, even if capable of working and anxious to work, first require treatment in the institution. In a large portion of cases, the general bodily condition is so poor that a long period of time must elapse before they will be in proper condition to undertake physical work.

The reward system of inducing patients to do out-of-door work by giving them beer, tobacco, etc., was taken into consideration, but not undertaken.

Taking the whole number of patients who engaged in out-of-door work, there were, out of 263, seventy men who could be relied on more or less. The percentage upon this basis would be 26.6. Taking another period of time, there were, out of 275 insane men, fifty-six who could be relied on to work regularly, or 20 per cent., and eighteen who would occasionally work well; giving altogether 27 per cent. as the proportion of insane men competent to work at farm-labor for a longer or shorter period of time.

This percentage seems to represent, as nearly as possible, the real proportion of insane men in a German

asylum who might be expected to render any real service as farm-laborers.

THE COST OF INSANE ASYLUMS.

Dr. Rayner² refers to the position taken by Dr. Hack Tuke, that small asylums are from an economic point of view better than large ones, and gives some tables of his own which seem to indorse this position. These tables are made up by dividing the whole of the county asylums into four classes: the first being asylums of not more than 450 beds; the second 450 to 600 beds; the third 600 to 800 beds; and the fourth 800 beds and upward. From the statistics given it appears that the large asylums cost £44.2 per bed more in construction, and £1.06 per bed annually in repairs more, than the medium asylum of 450 to 600 beds, and patients maintained in the former cost 6½d. per week more than in the latter. The medium-sized asylums (450 to 600) also have the advantage in the same comparisons over the asylums of 600 to 800 beds, in which it might have been expected that an increase of patients with little corresponding increase of staff would result in cheapness.

Dr. T. Claye Shaw, superintendent of the Middlesex Asylum, takes a different position in regard to the cost of large and small asylums.³ He says that, "It is to be expected that those asylums that have the most unfavorable statistics should cost the most, because in proportion as the population is more feeble the expenses for attendance and extra diet will be greater, and the recoveries will be fewer; and there can be no doubt that in proportion as an asylum is large, so does it get filled with unfavorable cases in a greater proportion than would have been the case had it been of moderate size and more select in its receptions." It does not follow that large asylums are always in themselves the most expensive, Prestwich and Hayward's Heath being examples to the contrary. Often small asylums receive scarcely any but curable cases.

The average cost per head cannot be taken as the measure of asylum proficiency. As death-rate and expense rise together, so do high recovery rate and cheapness go hand in hand with low death-rate. With the provision list in one asylum at five shillings and two-pence per week, and in another of nearly the same size at four shillings per week, the recoveries are not so numerous in the former as in the latter. The drug charge in the two asylums is the same; in the less favorable of the two the salaries and wages are much larger, so that medical and general attendance tell in inverse ratio to their quantity. The difference in the two asylums is owing to the nature of the asylum populations.

Primâ facia an asylum for 1000 or 1500 patients ought to be less costly than one for 600 or 700. There are, however, special reasons why this may not be the case. It will often be found that the smaller asylums err in want of accommodation; they may not have a proper chapel, recreation hall, or laundry, or the wards are too small and over-crowded, or they are deficient in heating and electrical appliances. The larger asylums are more complete in these respects.

It is difficult, however, to compare the expense of erection, as different building committees have very

² Relative Cost of Large and Small Asylums. By Henry Rayner, M. D., Medical Superintendent, Hanwell Asylum. *Journal Mental Science*, April, 1883.

³ On Large and Small Asylums, *Journal of Mental Science*, July, 1883.

¹ *Zur landwirtschaftlichen Beschäftigung der Irrenkleinere Mittheilungen. All. Zeitschrift f. Psychiatrie*, Band xxxix., Heft 6.

different ideas. In this and other ways it is almost impossible to compare asylums, and what will be true for one may not be true for another, or even possible.

Dr. Chapman continues the investigation of this subject in the same number of the *Journal of Mental Science*.¹ The conclusions at which he arrives are, he says, still unfavorable to the large asylums, but not so unfavorable as he supposed at first from more limited statistics. As to cost, one table shows that the cheapness of moderate-sized asylums is due not entirely to their size but also to the circumstance that they happen to contain a smaller proportion of active disease amongst their patients; if the tables may be implicitly trusted, about one third of the saving is due to this circumstance. In relation to recoveries, it is found that the rate has improved within the last few years. This improvement, however, is probably more apparent than real, as in some of the favorably situated asylums there is a real gain; while in the lunatic wards of work-houses there is, if anything, a falling off. The death-rates are principally affected by the proportion which the admissions bear to the average number resident.

As conclusions reached by the way are more firmly established, as well, perhaps, as of greater, if not more practicable, interest, than those bearing on sizes of asylums, may be noted:—

(1.) That a rapid increase in the proportion of asylums to the total number of lunatics of a district, which is more or less synonymous with the free admission to asylums of chronic cases previously kept in work-houses or at home, results in a low ratio of recoveries without any distinct effect on the death-rate, but probably slightly reducing it.

(2.) That the accommodation of a large proportion of the lunatics of a district in work-houses results in selected cases being sent to asylums, and consequently these asylums present higher rates of recovery.

(3.) That satisfactory recovery rates tend to go with satisfactory death-rates, and after allowing for such disturbing elements as noted above, and for certain asylums showing good rates at the expense of others, there is a probable margin due to efficiency.

PUNISHING LUNATICS.

In the January number of the *Journal of Mental Science*, Dr. R. W. D. Cameron published a paper on the Use of Restraint in Asylums, and, among other subjects, spoke of the effect of punishment on the insane. In the April number of the same journal there is one of those sharp and caustic editorials, which are somewhat characteristic of this journal, on the Punishment of the Insane.

"Punishment," the writer states, "is the positive infliction of suffering as a righteous result of wrongdoing, and as a deterrent from its repetition." But the wrongdoing of the insane is the result of their malady, which produces it either directly through delusion or indirectly by perverting their moral sense and relaxing their self-control.

There must be a broad and absolute distinction between treatment of criminals and treatment of the insane. "Better that some criminals should escape punishment under the shelter of insanity than that one insane person should be dealt with as a criminal."

"It was supposed that this principle was universally accepted, and it is, therefore, somewhat startling to be now told that when ordinary methods fail to induce a person to work the infliction of punishment is imperatively demanded in his own interest. The insane person, we are told, should be terrified by the use of hyoscyamine, should be compelled to swallow disgusting mixtures, or be shocked by plunge or shower baths, or be disfigured by cropping the hair, or degraded by ragged clothing, or burdened by heavy weights attached to the body."

The idleness, irritability, and turbulence of insane persons are a part of their malady. It would be as reasonable to punish an epileptic manifesting physical convulsions as to punish a lunatic for mental moods and explosions which are equally the result of disease. It is true that crime and insanity are often strangely mixed, and that some persons appear to be at certain times on one side, then again on the other of the narrow line which divides them. But punishment seems to harden rather than to benefit in these cases, and does nothing to develop self-control or promote recovery. Prison records show that punishments are futile when applied to such persons. Thus the only cases which in an asylum might afford the shadow of justification for punishment are just those in which it is worse than useless.

To punish by means of drugs is the saddest punishment of all; it is a degradation of medicine, and a double wrong to the patient.

Indulgences and rewards may sometimes be properly extended to the orderly and industrious inmates of an asylum, and withheld from those who will not exercise what self-control remains to them. Rewards, as a rule, do not go far enough. The judicious employment of a reward system tends to promote self-respect and habits of industry, and in many cases may lead to recovery.

"If the discussion of the subject of the punishment of the insane leads to a fuller recognition of the all-important one of providing them with employment, the writer of the present article will have no reason to regret that the pages of the *Journal* have been the channel of the expression of views which, to say the least, are liable to be misconstrued." Recovery very often begins from the time when the habit of daily occupation is reestablished. Employments of the most varied kind should be furnished for patients, those which are suitable for some being entirely unsuited to others.

In the concluding paragraph but one of this article the writer says: "In a word—and this is the sum of all the moral treatment of the insane—the appeal is to all that is sane in the man to conquer and correct all that is insane in him."

INSANE HOSPITAL ARRANGEMENT AT KANKAKEE.

The last report of the Board of Public Charities of Illinois² contains, as usual, much that is of interest with reference to the insane. Among other subjects treated of, that which is included under the heading of the Kankakee Hospital is of special interest.

At the time when, some thirty years ago, the cloister or monastery plan of building lunatic hospitals received the early indorsement of the Association of Medical

¹ On the Recovery and Death-rate of Asylums as Influenced by Size and Other Circumstances, by T. A. Chapman, M. D.

² Seventh Biennial Report of the Board of State Commissioners of Public Charities of the State of Illinois. Presented to the Governor, November, 1882.

Superintendents of Institutions for the Insane the lunacy question had not assumed, in America, its present vast proportions. The census of 1850 showed the number of the insane in the United States to be 15,610. The number of insane in hospitals probably did not exceed 4000, and the average number in each much more than 150. The census of 1880 showed the number of the insane in the country to be 91,846, and the number in hospitals 40,942. In twenty-five of the leading hospitals of the country the average number in each is now 525. The altered conditions of the problem require a new solution, and this solution is more likely to be found by the adoption of new rather than of antiquated methods.

In the general principles of construction and management of the hospital at Kankakee it is believed that some of the conditions of this problem have been at least partially solved. The general arrangement of the hospital, as is already well known, consists essentially of a large central building and various attached buildings built on adjoining lots. The interest of the experiment naturally centres in these buildings, which are not cottages. They are known as detached wards. They contain varying numbers of patients, the smallest of those already built containing thirty-five, and the largest sixty-four, patients. When the whole plan of the asylum buildings has been carried out there will be enough of these detached wards, together with the central building, to accommodate not less than 1500. The institution when fully developed will present the appearance of a village highly organized, thoroughly policed, in admirable sanitary condition, and under complete control.

An idea prominent in the organization of the Kankakee institution was the removal of unnecessary restrictions upon the personal liberty of the patients. From the large number of detached wards it is possible to much more largely individualize the treatment than in an ordinary hospital for the insane. One ward, for instance, may be locked, another unlocked; one ward may have barred windows, and another open windows; in one ward the patients may retire at eight, in another at eleven, etc.

The detached wards react upon the administration of the hospital in a singular way. The sense of responsibility on the part of attendants is increased when, in addition to taking away restraining apparatus, as is done in this hospital, the doors and windows are thrown wide open, thus necessitating increased vigilance. This sort of effect does not stop with the attendants, but extends to the officers and physicians in charge, for the success of the detached wards depends primarily upon the good judgment shown in the selection of the patients who are to occupy them, and to make this choice in the wisest manner the medical officers are obliged to observe their patients more closely as individuals.

With a complete system of detached wards the discipline of the hospital can be easily maintained by the simple exercise of the power of transfer from one ward to another.

An institution arranged in the manner that this one is will require a greater number of assistant physicians than an ordinary hospital for the insane.

It has been undertaken to separate at Kankakee, more than is usual, the functions of the financial from those of the medical head; but as it is evident that the administration of the business affairs and the govern-

ment and discipline of so large a hospital must occupy the entire energies of one man, it will be seen that the direct medical treatment of patients must be intrusted by the superintendent to his first assistant. This assistant should be unusually well qualified, and paid a liberal salary. The other assistants should be scattered among the different detached wards, and the superintendent should live in a house separate by itself. Two criticisms upon the hospital are offered by the writer, the first being, that the main ward building, which accommodates three hundred patients, is too large and prominent. A better result would have been attained if no central building had been erected, and the wards designed for recent and curable, or refractory and troublesome, patients had also been detached. The other criticism is, that buildings for the same purpose might have been erected at a less cost. The limit of economy in building has probably not been reached as yet.

SPANISH INSANE ASYLUMS.¹

Dr. Seguin visited fifteen of these asylums, and gives an interesting account of his visit. He found the Spanish physicians in charge of asylums very much behind the times in their knowledge of insanity, but they were willing to acknowledge that such was the case, which, Dr. Seguin thinks, promises well for the future.

Most of the asylums were over-crowded, badly arranged, badly ventilated, badly heated, and in general, badly managed. The patients in some of the asylums were filthy. In most they had little or no occupation or amusement provided for them, though occasionally a billiard table was found in one of them, and perhaps a piano, though never in use.

One of the best-managed of the private asylums was apparently that of Dr. J. M. Esquerdo, near Madrid. Dr. Esquerdo is one of the most eminent of the alienists of Spain.

This asylum contains about sixty inmates. The buildings are arranged to form a double square; one being for men and one for women. Each side of the house has its own gardens and yards, called "patios," which are similar to those which are found in the ordinary houses of South Spain. Patients pay from \$25 to \$100 per month, and have rooms accordingly. The rooms are heavily locked and barred.

The female patients of each class eat separately, but the male patients have their meals in the same room. Each class has a different table, with a different quality of food and wine, except that all have one kind of bread.

Dr. Esquerdo uses very little restraint.

One of the oldest asylums in Europe is the Provincial Asylum of Zaragoza, having been founded in 1425. It contains 430 patients, and is very much over-crowded. Thirty epileptics are isolated in a wing by themselves. No restraint is used, but patients are isolated in small, ill-lighted, and wretched rooms.

For the purpose of erecting a new asylum for Zaragoza, \$600,000 have been appropriated. The land has been given. The buildings will be arranged in pavilions to accommodate each one hundred patients. It is intended to build eight of these pavilions.

The oldest asylum of Western Europe is that at Valencia, which was opened in 1409. It is called El

¹ Notes on Spanish Asylums for the Insane. By E. C. Seguin, M. D. *Journal of Nervous and Mental Diseases*, July, 1883.

Manicorno de Jesus, and is situated near the gate of San Vicente. The building is an altered convent, and not the original building. There are 530 inmates. The rooms for the epileptic, violent, and filthy patients, are very bad. Restraint is greatly abused. In this regard the asylum is a century behind the times. Camisoles, muffs, etc., are used; but, what is worse, there is an iron belt, made in two segments, connected behind by a hinge, and in front by a screw and nut. On either side, secured by a rivet, is an iron oval chain link, two inches long, to which is attached an iron manacle or bracelet, opening with two hinges, and secured by a screw and nut. The whole apparatus weighs from four to five pounds.

The worse thing of all at this badly managed asylum is the way in which the filthy demented patients are treated. In one long, narrow, dismal room Dr. Seguin found between thirty and forty women squatting, nearly naked, on a wooden platform about six by twenty-five feet, and raised one foot from the floor. On the other side of the same hall, a yard away, perhaps, was another sloping wooden platform extending the length of the room and covered with corn husks and straw. On this these unfortunate patients passed the night side by side. A bad-looking man, assisted by a woman, had charge of the room.

In the conclusions with which Dr. Seguin concludes his paper, he states that at a guess he would estimate the total number of the insane in Spain, including cretins, idiots, epileptics, etc., at about 15,000.

He found that the percentage of cases of general paralysis varied according to the observer from two to twenty-five per cent. The disease has greatly increased within the last fifteen years. As to the cause there was a difference of opinion, alcoholism alone, or combined with syphilis, as well as over-intellectual exertion or mental strain consequent on the increasingly severe struggle for a living, all being assigned as the cause.

There is no special fault to be found with the best private asylums of Spain, except that the violent and filthy patients are not treated with enough patience and humanity, and the male patients do not have pleasant and cheerful rooms to meet in. The provincial asylums are all bad.

THE USE OF STIMULANTS IN INSANE HOSPITALS.

The *Journal of Mental Science* again calls attention to this subject.¹ There is no doubt that stimulants are less used in English asylums than formerly. There are now twenty-seven pauper asylums in England known to the editors of the *Journal*, where beer has been given up as a beverage. Dr. J. A. Campbell, of the Cumberland and Westmoreland asylum, after several years' trial, is satisfied that patients are much better without it, and Dr. Rutherford of the Lenzie Asylum, who has many out-of-door workers, gets along without it. Dr. Lindsay, of the Derby County Asylum, does not use beer as a beverage, not only considering patients better without it, but also thinking that the habit of drinking is sometimes fostered by its continued use in the asylum. He has greatly diminished the use of stimulants in the treatment of disease, substituting milk, arrowroot, and other nutritious articles of food. The general health of the inmates seems better than before.

At the Glamorgan County Asylum milk has been substituted for beer with good results among the pa-

¹ The Beer Dietary in Asylums. July, 1893.

tients. The female attendants were allowed a money equivalent, and the males a uniform.

Several other institutions are spoken of where the results have been good. It is to be hoped that the movement now in progress will lead to the general adoption of a more liberal and nutritious diet for the insane in this country as well as in England. If such is the case we shall undoubtedly see a time when stimulants will rarely be needed.

Reports of Societies:

NEW YORK ACADEMY OF MEDICINE.

A PROTEST BY DR. J. G. ADAMS.

At a stated meeting of the Academy held Thursday evening, November 1st, DR. JOHN G. ADAMS read a protest against the adoption of so much of the minutes of the preceding meeting as referred to the passing of the resolution offered by Dr. Loomis to rescind the resolutions of Dr. Flint, in regard to the admission of new members adopted by the Academy at the last meeting before the summer vacation, on the ground that the motion to rescind was clearly out of order, and should not have been entertained by the Academy. Among the reasons which he gave were the following: That a question once put to a deliberative body could not again be acted on except by a motion to reconsider. That section 6 of the Rules of Order of the Academy directed that after any question had been decided, except one of indefinite postponement, any two Fellows who voted in the majority might, at the same, or next stated, meeting move for a reconsideration thereof; without which no discussion should be allowed.

The fact was, that two Fellows who had voted in favor of Dr. Flint's resolutions had moved for reconsideration, which was agreed to, and the Academy had then decided to indefinitely postpone the reconsideration. That the motion to rescind was, therefore, unparliamentary, and that under the rulings of the chair motions could be adopted and rescinded in the Academy without regard to rules of order. Dr. Adams claimed, consequently, that the adoption of Dr. Loomis's resolution was a direct violation of the By-laws, and submitted that the action of the Academy on it was null and void.

DR. T. HERRING BURCHARD read a memoir of

THE LATE FREDERICK D. LENTE,

Corresponding Fellow of the Academy of Medicine, in which he paid a feeling tribute to the many noble qualities, and high professional attainments of the deceased; after which the paper of the evening was read by DR. FESSENDEN N. OTIS, on

THE RAPID EVACUATION OF STONE FROM THE BLADDER AFTER CRUSHING—WITH PRESENTATION OF A NEW AND SIMPLIFIED EVACUATOR.

After stating that the revolution which had been going on for the last five years in regard to lithotripsy was now complete, and that the procedure advocated by Professor Bigelow had already been formally accepted by all the authorities of Europe and America, he quoted from the paper read by Dr. Bigelow at the International Medical Congress in London in 1881,

and spoke particularly of the modesty with which the latter had alluded to his own illustrious achievements. From the time of Civiale, he said, down to the year 1878, there had been little change in the manner of operating for stone in the bladder by lithotrity. The duration of the sittings were as brief as the skill of the surgeon, with the fear of cystitis always before his eyes, could make them; while the use of anæsthetics was exceptional. Now, however, anæsthetics were used as the rule, and the sittings had even been extended to three hours without injury to the patient.

Dr. Otis* then proceeded to describe the original evacuator of Sir Philip Crampton, devised in 1846, and exhibited a diagram of it. Diagrams were also constantly referred to in describing the later instruments of various operators. Crampton's evacuator was modified by Mr. Clover, of London, who attached a receiver of glass to the rubber bulb; and to this modified apparatus he subsequently added a vertical receiving chamber. Professor Bigelow had paid a willing tribute to the efficiency of this instrument, which was the only one of any value in existence before his own. His own success in lithotrity, he said, depended in some measure on the fact that the tolerance of the bladder had been established; but the chief point about his method was the use of a large catheter, whether straight or curved.

Between Clover and Bigelow, however, Dr. Otis continued, there was a distinct hiatus, and this he claimed himself to have filled. Up to 1874 the normal calibre of the male urethra had been regarded by all authorities as twenty-one millimetres. In 1874 he had invented his urethrometer, and with it had demonstrated, beyond the question of a doubt, that the normal calibre was thirty-two millimetres. Professor Bigelow had said, in his earliest monograph, that whether or not the position of Otis was adopted, there could be no doubt that the urethra would admit a much larger tube than that commonly attached to the Clover or the French instrument; and at the International Medical Congress of 1881 he had declared that the smallness of the catheter employed in lithotrity had delayed progress in the operation for half a century. The hiatus, Dr. Otis believed, was thus satisfactorily filled by the determination of the true calibre of the urethra.

As regards the extension of time employed in performing lithotrity, as long ago as March, 1876, he had operated in the case of a patient sixty-four years of age, affected with a phosphatic calculus, whom he had seen in consultation with Dr. Mann, of Brooklyn, and had occupied an hour and ten minutes in the crushing and removal of the stone. In November, 1877, he had occupied an hour and a quarter in a similar operation at Sag Harbor, Long Island, and he felt sure that many other surgeons had had the same experience before Professor Bigelow published his first paper. He claimed, therefore, that the latter did not discover the tolerance of the bladder under surgical procedure. Bigelow did much more than this, he said. He utilized all the points of knowledge that had been previously gained in regard to this whole subject, and achieved one of the most brilliant surgical triumphs of modern times.

The smallest catheter that ought to be used in the operation, he thought, was No. 27, of the French scale, and the largest, No. 32. The relation of the size of the urethra to that of the penis was practically

invariable, and if in any case there was any deviation from this fixed relation it was abnormal. He had seen some cases in which the urethra was larger than the size indicated by that of the penis, but not a single one that was smaller, unless it were narrowed by stricture or other abnormal condition. It was very important before operating to get the urethra in the best possible condition, as the great danger was the liability to injure its deep portion, and consequently, if there were any obstructions they should, by all means, first be removed.

Professor Bigelow believed that the evacuating tube should not be less than twenty-five, or more than thirty-one, millimetres in circumference. It was surprising what a great difference a very few millimetres made in the capacity of the tube for quickly passing the debris. Thus, in an experiment which Dr. Otis had made with crushed coral, a substance which very admirably represented the mixed calculus, a catheter of thirty millimetres calibre carried 300 grains in thirty seconds, while in the same length of time a tube of twenty-seven millimeters carried only 180 grains. The tube should be two or three sizes smaller than the urethra, and Bigelow preferred the straight catheter to the curved. The objection to the straight instrument was the greater difficulty of introduction, especially where there was any prostatic enlargement, and in order to facilitate the introduction in the latter class of cases Dr. Otis had devised a straight catheter with a small curve just at the extremity.

Although Professor Bigelow had insisted that a large catheter was the one great requisite for successful lithotrity, he believed that an important factor in the success of the operation had been the more powerful evacuating instrument that he (Bigelow) had been the first to employ. The objections to Bigelow's first instrument were that it permitted more or less return of the debris, and the too free passage of air into the bladder. In 1879 Sir Henry Thompson devised an apparatus in which the debris dropped directly into a receiver below, and in which there was a metallic, instead of flexible, connecting tube provided with a stop-cock. This was open to the same objection of allowing a return of the fragments into the bladder, and, accordingly, in 1880, he made some changes in it with a view to prevent this. The main idea of Sir Henry Thompson was to get as short and direct a route as possible between the bladder and the receiver. As to Professor Bigelow's early instrument, Dr. Otis had used it for a long time, and almost always with the most satisfactory results, and in the present year Mr. Reginald Harrison, of Liverpool, had stated that after trying several modifications he could not but express his satisfaction with Bigelow's original instrument. But Bigelow had from time to time been improving his instrument. Thus he modified it so that the fragments entered the bulb at the side, and not at the top, of the bulb, and also introduced a ball-valve and strainer to prevent the return of the fragments. The device was efficient, but rendered the apparatus more complicated, and added greatly to the expense as well as to the length of the route between the bladder and receiver. After speaking of various other modifications which had been made Dr. Otis stated that in the early part of 1883 Professor Bigelow had achieved a signal success with his latest instrument (which he exhibited), in which the route of the fragments was greatly shortened, and the return of the debris was

prevented by a strainer prolonged to the centre of the bulb. He had used this instrument on one occasion, and its action seemed to be perfect. Sir Henry Thompson's latest instrument, in which the route was as direct as possible, was also described.

Dr. Otis then went on to say that the weight and expense of the Bigelow and Thompson instruments had occurred to him as objections, and accordingly he had devised, with the assistance of Messrs. Tieman & Co., an apparatus which was lighter, simpler, and much less expensive. It consisted of a bulb of strong, annealed glass, two inches in diameter, into one side of which a metallic tube, connecting with a rubber air-bulb, was introduced, the tube extending up to near the top of the chamber. On the other side entered the tube from the evacuating catheter, which curved downward, and was designed to carry the debris nearly to the bottom of the bulb, below which was a glass receiver attached by a strong bayonet joint. A stop-cock cut off the entrance of air into the bladder. The apparatus could be filled either by pouring water into the bulb or by first exhausting the air from it, and then allowing it to fill itself. Having described the instrument, Dr. Otis exhibited its mode of working by introducing the evacuating catheter connected with it into a bottle representing the bladder, which contained a considerable quantity of crushed coral to represent the debris of a calculus. In a short time all the fragments of coral were successfully carried to the receiver, and there was no return of them whatever into the bottle representing the bladder. The fact that there was no tendency to return was stated to be due to the direction of the current, depending on the relative position of the orifices of the two tubes in the bulb. In this instance a catheter of thirty millimetres calibre was used. It was explained that no strainer or other apparatus was required to prevent a return of the debris into the bladder. This was certainly an advantage because the strainer was liable to become clogged with mucus, and it was essential that it should always be kept very clean. In conclusion Dr. Otis said that he had ascertained that his instrument could be made for exactly half the price required for Dr. Bigelow's.

The President, DR. BARKER, remarked that it might be of interest to state that the oldest living physician in Boston, who was also a professor at Harvard, had recently been relieved of a very troublesome calculus by Dr. Bigelow's operation. He also read a letter of regret at not being able to be present from Dr. James L. Little, who said that he had performed the operation a large number of times with very gratifying success, and that in his last case he had crushed a stone an inch and a half in diameter in a patient seventy-seven years of age.

DR. EDWARD L. KEYES, being called on by the chair, remarked that he did not think Professor Bigelow had ever made any claim to have discovered the tolerance of the bladder. This was one of the first things that Civiale and others had found out in their operations. Civiale sometimes occupied half an hour with a sitting, but as he could not evacuate, and as his instruments were comparatively rough, he found by experience that it was much more advisable to employ only short sittings. As to the increased size of the tube now employed, he thought this was undoubtedly the result of the researches of Professor Otis in regard to the calibre of the urethra; but although Professor Bigelow claimed that this was the essential point in the success of his

procedure, he did not believe that such was really the case. The birth of lithotripsy in the brain of Bigelow was due to a crystallization of all the ideas contributing to that grand result which had previously existed in the profession, and one of the principal elements in its success was the increased efficiency of modern instruments. The operation could be performed perfectly well with a No. 12 tube, English scale; though, of course, the larger the tube, the shorter would be the time required for the evacuation. He had never yet had occasion to cut a urethra as a preliminary to the operation, except just at the meatus; but if he had a case of stone with organic stricture of the urethra, he would prefer the external incision to lithotripsy. So far as he knew, the only operators of high authority who used very large tubes were Bigelow, Otis, and Harrison; most others fearing that possible injury to the urethra might result from their use. As to Professor Otis's new instrument, he had seen it for the first time only that morning; but, as far as he could judge, it would add, if possible, to the professor's already brilliant reputation for mechanical ingenuity. Its efficiency, simplicity, cheapness, and portability, seemed to him simply admirable, and among its special advantages were the substitution of air-pressure for water-pressure, and the fact that the glass bulb enabled the operator to see the exact condition of affairs at all stages of the operation. Whether the apparatus would work as efficiently where there was a quantity of fine phosphatic dust to be evacuated, as in cases where the fragments of calculus were larger, he was not prepared to say.

DR. OTIS, in reply to Dr. Keyes, stated that he thought that Sir Henry Thompson ought to be added to those who sometimes, at all events, resorted to the larger tube, as he had repeatedly used a No. 30. When there was prostatic enlargement it was necessary to proceed with great caution, and he himself always inculcated the rule to use as small an instrument as would evacuate the fragments in such cases. When it was necessary to incise the meatus or cut a stricture as a preliminary to lithotripsy, it was always advisable to do this some little time before the main operation, so as to allow the parts to heal before the latter was undertaken. It was his practice always to clear the urethra of obstructions, if any existed, before performing lithotripsy. In regard to his instrument, the advantage of having so small a bulb was on account of its portability and the diminished danger of its breaking. He had omitted to say that whenever it was desirable, the apparatus could be inverted and the bulb filled directly with water.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

C. B. NANCREDÉ, M. D., RECORDER.

STATED meeting, Thursday evening, September 27, 1883. The President, DR. JAMES TYSON, in the chair. DR. SEILER presented a specimen of

POSTERIOR NASAL HYPERTROPHY IN SITU, TOGETHER WITH AN EXOSTOSIS FROM THE VOMER.

The anatomical relation of the parts on the right side of the nasal cavity was perfectly normal.

When, however, this partition was removed, a very marked enlargement of the posterior end of the lower turbinated bone on the left side was noticed, which proved to be a posterior hypertrophy.

On the left surface of the vomer a projection was also seen, which proved to be an exostosis, the existence of which, in nasal disease, is denied by some authors. The tumor-like projection into the nasal cavity consists of a hypertrophy of the erectile tissue underlying the nasal mucous membrane.

Its presence is due to a long-continued catarrhal inflammation which, by the infiltration of its inflammatory products into this cavernous tissue, has distended the venous sinuses, and has increased the thickness of the connective tissue walls of the caverns, so that when they are empty of blood a perceptible swelling or tumor still remains, as is seen in the specimen.

The reason why these hypertrophies occur more frequently at the anterior or posterior ends of the lower turbinated bones must be looked for in the fact that the blood, favored by gravitation, distends the caverns of the erectile tissue more easily under the excitement of local irritation in these localities, and that the anterior as well as the posterior ends of the lower turbinated bones, forming the entrance to the in- or outgoing air current, are more liable to irritation by irritants contained in the respired air than any other portion of the nasal cavity.

Dr. Seiler said that, of late, great interest had been taken in the pathology of hay fever, particularly in its relation to the pathological condition of the nasal cavities, and that great success had attended certain methods of treatment. In hay fever there is general hypertrophy of the mucous membrane of all the turbinated bones and septum nasi. The membrane is thickened and puffed up, thus occluding the nasal cavities. The inhalation of impure air, dust, etc., will produce irritation and cause asthmatic attacks. The pressure exerted by foreign growths or hypertrophied normal tissue in the nares also causes asthmatic symptoms.

As regards the possibility of cure, we may say that all sufferers from hay fever invariably have hypertrophic nasal catarrh, and if you, during the winter, remove the hypertrophied tissue the hay fever will not return during the summer. This removal is done either with a dental drill or the cautery knife.

He did not believe it to be due to rotten grains, as the worst cases occur in traveling from coal-dust, etc. The disease is due chiefly to the hypertrophies. Sometimes the attack comes on frequently, and lasts only a very short time, the patient in the mean time being well. He had seen a number of such cases. In one case a young lady was attacked at every menstrual period, the disease lasting a half hour. There was every symptom present: sneezing, watering of the eyes, running and clogging up of nose, difficulty in breathing, etc. In another instance, a gentleman had the same kind of seizures, but they were accompanied with intense pain in the nose. By surgical means he succeeded in relieving him very much. Instead of one attack in three or four days, he has had but one in four months. These cases show how localized hypertrophies can produce spasmodic attacks.

DR. J. T. ESKRIDGE presented specimens of

MALIGNANT GROWTHS OF THE STOMACH AND OVARIES,

with the following history:—

Mrs. A., aged thirty-two years; married; born in Germany; had done hard service-work all her life. She had had two children, both living and healthy; three

and two years old respectively. Her husband was a drunken, dissipated fellow. Her children were born at term. Neither she nor they presented any evidence of syphilis. She had had no abortions. Her confinements had been normal. After the first she remained in bed ten days, but after the last only five, as she was compelled to go out washing to earn bread for herself and children. Until her last confinement she had always felt well, and weighed, two years ago, one hundred and forty pounds; but soon after the birth of the child she began to lose flesh and strength. So far as she knew, none of her relatives had suffered from cancer or tuberculosis. In the latter part of the year 1882, she fell on her stomach and hurt herself considerably. Soon after the accident her abdomen became painful and began to swell. In March, 1883, she was admitted to the Episcopal Hospital. She remained in that hospital several weeks, and during her stay there her abdomen was twice tapped, a large quantity of a straw-colored serous fluid having been drawn off each time. She entered the hospital of the Jefferson Medical College, very much emaciated, July 1, 1883. Dr. Getchell twice drew off large quantities of fluid similar in appearance to that obtained from her while she was in the Episcopal Hospital. She came under my care July 17th. She was very weak, and her appetite was poor, but her stomach was tolerant, and had been so during her entire illness. Her abdomen was greatly distended, and slightly painful to palpation. No nodules could be felt in any portion of the abdominal cavity. No heart or lung trouble was detected. The urine was normal in appearance and quantity. The temperature over the abdomen was a little higher than in the axillæ, in each of which it was 99.4° F. A few days later, about three gallons of a yellowish serous fluid were drawn from the abdominal cavity. After the operation the abdomen was flaccid and tolerant of manipulation. A tumor just below the ensiform cartilage of the sternum was felt. It was thought to be connected with the stomach. A tumor, much larger on the right side than on the left, was observed in each ovarian region. The liver and spleen presented, so far as I was able to detect, no evidence of disease in these organs. Occasionally she was troubled by diarrhoea. She grew weaker, and her abdomen more tender. She died from asthenia, August 1, 1883. Her stomach remained tolerant to the last. From July 27th to August 1st, her temperature ranged from 100.4° to 102° F. She was treated mainly with anodyne and supportive measures. Anti-syphilitic treatment was at one time employed, but without any improvement.

Sectio Cadaveris (twenty-one hours after death). Body greatly emaciated, the adipose tissue being almost completely absorbed. Parietal layer of peritoneum thickened, opaque, and quite firmly attached to abdominal muscles. Its internal surface is very rough, and presents a rugose appearance almost as well-marked as the mucous membrane of a healthy stomach. The rugosed surface is made up of layers of firmly adherent lymph, and is studded throughout with deposits of pigment. The peritoneal cavity contains about one and a half gallons of a straw-colored serous fluid. Bowels are distended with gas, and variegated externally by deposits of old lymph. Stomach is distended with fluid. It is very small, capacity not more than a pint. It is firmly bound to all adjacent structures by bands of old and recent adhesions. Externally it presents the appearance and feel of an old cystic kidney.

Its length is about eight inches; greatest breadth three inches. The walls of the pyloric two thirds of the stomach vary from three fourths of an inch to one quarter in thickness, the calibre of this portion not being more than one and a half inch in diameter. The mucous surface is smoother than normal, and anæmic in appearance. While the growth encircles the stomach at its pyloric end (two thirds), its thickest portion is along the lesser curvature. The walls at the cardiac end of the stomach are thinner than normal, easily torn, and present several ecchymotic spots. The pyloric orifice is greatly dilated, and admits of all the fingers of one hand being passed up to their second joint.

The calibre of the upper portion of the duodenum is two or three times larger than normal. The walls of the bowel at this point are thickened, but the thickening does not extend more than two or three inches when the bowel resumes its normal appearance. General adhesions are found, binding together the greater and lesser bowels, but at no point are their calibres materially lessened. The *caput coli* is much enlarged, and its appendix is curled upon itself, presenting a snail-like appearance.

A spherical growth, about five inches in diameter, is connected with the right ovary. About two thirds of the tumor is formed by a cyst whose walls are about an eighth of an inch thick. The inner surface presents a cheesy appearance from broken-down exudated lymph. The contents of the cyst are a dark, muddy liquid. The remainder of the tumor is made up of a caseous-like substance, in which a cyst about the size of a walnut is found. Connected with the left ovary is an ovoidal growth, about three inches in length and two in breadth. The tumor is made up of a fibro-fatty substance. The womb is quite small, and apparently is not the seat of any disease.

The stomach seems to be the point of chief interest in the above case. The absence of nausea, vomiting, eructations, and other symptoms of gastric indigestion, in a contracted stomach, the pyloric two thirds of whose walls are infiltrated by a neoplastic growth, can be explained only, I think, by the presence of the enormous dilatation at the pyloric orifice. This condition of affairs permitted indigested food to pass from the stomach into the bowel readily. Gastric digestion was apparently almost *nil*, the fluids in the intestine performing their own function and that of the gastric juice.

It is probable that the growth in the stomach is secondary to those of the ovaries, and that the peritonitis followed by ascites was occasioned by the fall received eight months before the death of the patient.

THE PRESIDENT said that he had never seen a case of disease of the stomach with so much thickening of walls and contraction of the cavity combined with so much dilatation of the pyloric orifice.

DR. FORMAD said that, judging from the specimen, without a microscopic examination, he did not think there was any trace of cancer either in the ovaries or stomach. It looked more like a case of chronic fibroid gastritis. He has seen several cases of that kind. They are described and figured by Thierfelden in his *Pathological Atlas*. He also has in his possession a specimen of the affection. The ovaries also look fibrous, and malignant disease of the ovaries is usually sarcomatous. In fibroid disease of the stomach the muscular coat is affected by fibroid changes, as is also the mucous coat.

DR. ESKEIDGE, in reply, said that after examining the specimen carefully he felt that he would not be justified in calling it either sarcoma or carcinoma, and so called it a "malignant growth." There were no metastases. There was an absence of vomiting, notwithstanding the extent of the disease.

THE PRESIDENT said that in one of his cases, with all the symptoms of cancer of the stomach, post-mortem examination showed what was called fibroid thickening by one pathologist, but which Dr. Formad and himself regarded as cylindrical epithelioma.

The specimen was referred to the Committee on Morbid Growths for examination.

DR. DE SCHWEINITZ also exhibited specimens of

RECURRENT SCIRRUS OF THE MALE BREAST,

taken from the person of Moses W., aged sixty, a native of Ireland, and at the time of operation an in-patient in the University Hospital. He was of dark complexion, had a somewhat cachectic look, of bilious constitution, and rather melancholic temperament. His family consisted of ten members. Father and mother died in old age; of his brothers and sisters he had little knowledge, but, as far as he knew, none of them ever suffered with carcinoma in any form. Four and a half years ago a small kernel appeared beneath his left nipple. Gradually the nipple retracted, and the tumor slowly increased in size, until, at the end of a year and ten months, its dimensions were those of an orange. He then applied for treatment, and a Belfast surgeon removed the growth. Eight months later the growth began to recur in loco, the first nodule appearing in the scar at the point where a stitch was passed in the approximation of the wound. During August of this year he came to the University Hospital, and Professor Ashhurst removed the secondary growth, and also some enlarged axillary glands, which the patient claims were present at the time of the original operation. The patient denied any injury or inflammatory trouble in his breast previous to the appearance of the original tumor. He also denied that this breast had been larger than its fellow, or that it had ever secreted milk. Macroscopically the growth is seen to be composed of two portions, the one, larger, is a fibrous mass, rising above the level of the epidermis, brownish-red in color on the surface, and yellowish-white within, and of moderate consistence. The skin in the immediate neighborhood at the time of operation was of a dusky hue. The other and smaller portion is a nodule situated beneath the skin in the subcutaneous connective tissue, and is of similar color and consistence. A section under the microscope shows a connective-tissue frame-work, composed of round and oval alveoli, and scattered through it some spindle and round cells. These alveoli are quite closely packed with polymorphous epithelium, but chiefly of a spheroidal type. Much yellow elastic tissue is present in all sections. The skin in the neighborhood of the larger mass is involved in the carcinomatous process. The tumor is an ordinary scirrus or spheroidal-celled carcinoma.

It is needless to speak of the interest which attaches to carcinomata of the male breast, and of their infrequency of occurrence when compared with similar growths in the female mammary gland. I need only refer to Prof. S. W. Gross's interesting exhibit and remarks upon this subject in this Society's Transactions, vol. vi. I have mentioned that the tumor recurred at the point where a stitch was passed. It is

permissible to speculate whether, if the surgeon's knife had removed a larger area of skin, this local recurrence would have been prevented or at least delayed. It would not be an uninteresting study to make sections of the edges of flaps that are about to be approximated after the removal of malignant growths, and note whether any morbid manifestations would present themselves, ready to be lighted up in active growth by any irritation, as in this instance, by the passage of a suture. At all events this may serve the purpose of another warning that all incisions for such purpose should be carried as far into healthy tissue as is possible.

DR. W. E. HUGHES presented some specimens from a case of

PHTHISIS WITH ABSENCE OF PARIETAL PERICARDIUM
AND MALPOSITION OF LIVER,

with the following clinical history: C. L., white, aged thirty-three, was admitted to the University Hospital, July 21, 1882. He had been previously in the Philadelphia Hospital, under the care of Dr. E. T. Bruen. By occupation a carpet weaver, he had done of late years general laboring work, often much exposed to weather. He had been a moderate drinker and user of tobacco. There was a distinct history of asthma in the family, both mother and maternal grandfather having been affected, but no phthisis. When eleven years old he had pneumonia, and since then winter cough. Till three years before being seen he was well and strong, then the cough became continuous, and flesh and strength began to fail; a year afterwards dyspnoea developed; at first produced only by exertion, it soon became constant, and a most urgent symptom in the case. In the fifteenth month preceding admission to the hospital he had had two or three attacks of excruciating pain about the fifth interspace to the right of the sternum. The attacks would begin suddenly, last a few minutes, and disappear as suddenly as they came, leaving him completely exhausted. On admission to the hospital he was weak, somewhat emaciated, breathless, face sallow, with a circumscribed flush on left cheek. Expression cheerful. Left pupil larger than right; both responded well to light. Cough constant, rather dry; some muco-purulent expectoration in the mornings; dyspnoea constant, with marked exacerbation on exertion. Appetite and digestion poor; bowels irregular. On the right side of the chest a distinct prominence, reaching its greatest elevation at the fifth interspace, midway between the sternum and nipple. Over right chest poor movement, with flattening at the apex. At the apex there were evidences of a cavity, while from the third rib to the base, and from the sternum to the anterior axillary line (over the area of prominence just spoken of), there was flatness, with absence of vocal resonance and fremitus; posteriorly, dullness with mucous râles and scattered friction sounds.

On the left resonance was impaired at the apex, and respiration blowing, elsewhere normal. The apex beat of the heart was in the fourth interspace, one half inch outside of the left nipple. With the systole could be noticed a slight localized retraction of chest wall immediately inside the apex beat. Cardiac dullness extended from the right border of sternum two inches to the left of the sternum in the second interspace, two and a half inches in the third, and three and a half inches in the fourth. First sound weak and valvular. Second pulmonary sound accentuated and re-

duplicated. Liver dullness extended to the margin of the ribs anteriorly, continuous above with the flatness in the chest; posteriorly it was normal. A diagnosis of chronic plastic pleurisy with consequent phthisis was made, and the needle of an aspirator introduced about the middle of the area of flatness with negative results. The needle, as was shown after his death, must have punctured the liver. While in the hospital his condition remained much as it was on admission. A most interesting symptom was one connected with the pupils. They were usually unequal, sometimes the right, sometimes the left, being the largest. When first seen the flush was limited to the cheek corresponding with the largest pupil.

March 15, 1883. After a fall he had a slight pulmonary hæmorrhage, and died in fifteen minutes of apnoea, the heart continuing to beat after the respirations had ceased.

Autopsy (twelve hours after death). The upper right lobe of the lung had been converted into a cavity with contracting walls. The upper part of the middle lobe had undergone marked fibroid change. The rest of the middle lobe and all of the lower were collapsed, congested, pushed back by the liver, which lay in front of them. The lung was universally adherent to the chest wall and diaphragm. The left lung had small masses of cheesy deposit at its apex, with the remaining substance healthy. It was less adherent than right. The heart was normal in size and position. The valves and great arteries were normal. What lends the case its chief interest was a complete absence of pericardial sac, the heart lying free in the left pleural cavity, its surface in contact with the left visceral pleura. Toward the apex there were a few fibrous bands connecting the heart with the lung and diaphragm (evidently the results of old pleurisy), while toward the base it was impossible to separate the heart and lung on account of the density of the adhesions. The serous covering of the heart was directly continuous with the visceral pleura. From the diaphragmatic pleura immediately beneath the heart was a fold of serous membrane one inch broad, three inches long, apparently an abortive attempt at the formation of a pericardial sac. No such formation could be demonstrated at the base, on account of adhesions between the heart and lung. The liver presented a curious departure from the normal position. The right lobe about its middle turned sharply upon itself, and, carrying the diaphragm with it, extended upward to the third rib. This accounted for the prominence and dullness in the chest before noted. The gall-bladder was carried with the liver, its fundus pointing upward. The left lobe was very small, and was not carried up with the right. On section the liver showed a nutmeg appearance. The other organs were normal.

DR. EDWARDS said that the misplaced liver had been punctured several times by the attending physician, while he was his resident. The idea was to see if there was any accumulation of fluid at the place on the chest where resonance was absent.

DR. ESKRIDGE said that he had a case in which he thought the pericardium was incomplete, but he came to the conclusion that it was normal; the anterior layer of the pericardium having been removed along with the sternum, to which it was afterwards found attached.

DR. FORMAD said that he helped to make the autopsy, and was perfectly sure that the parietal layer was

absent. On removal of sternum, the heart was visible. The parts were very carefully investigated. The heart was seen lying in the left pleural cavity. On looking up the literature, he found in Virchow's *Archives* three or four such cases recorded. In this case there was some anomaly of the diaphragm and displacement of the liver. There was a healed plithistical cavity at the top of the right lung, and it is possible that in healing the scar may have caused the retraction of the diaphragm and ascent of the liver.

DR. MUSSER had had two cases in which marked retraction of the chest wall occurred at each heart-beat. In these cases there were no pericardial adhesions. Clinically, he regarded retraction of the chest walls as of no value in the diagnosis of pericardial adhesions.

DR. WOODBURY said that he saw in the Pennsylvania Hospital, two cases of absence of a part of the pericardium. One was congenital, and the other was due to inflammatory action. In the specimens presented this evening, there may have been inflammatory adhesions early in life, and later on rupture of these and of the pericardium.

Recent Literature.

Transactions of the Colorado State Medical Society at its Thirteenth Annual Convention, held in Denver June, 1883.

Transactions of the New Hampshire Medical Society at its Ninety-Third Annual Session, held at Concord, June 19, 20, 1883.

These two pamphlets, representing the work of one of the oldest and one of the youngest State societies, present an interesting ground of comparison, and suggest that Colorado, though a new State, has drawn its population from the oldest centres of civilization, and in medicine, as in other departments, has many workers of first-rate ability. Among the contributions we notice a careful analysis of Signal Service statistics with reference to Colorado climate, by Dr. Samuel A. Fisk, of Denver, in which the writer supplements his personal experience as a valetudinarian by figures showing the relative humidity, temperature, and other elements which contribute to give Colorado climate the value which many have found in it for incipient phthisis. In the New Hampshire volume we notice as of special interest the presidential address of Dr. A. H. Crosby, of Concord, N. H., and the other contributions are of value.

A Text-Book of General Pathological Anatomy and Pathogenesis. By ERNST ZIEGLER, Professor of Pathological Anatomy in the University of Tübingen. Translated and edited for English students by DONALD MACALISTER, M. A., M. B. New York: William Wood & Co. 1883. 371 pages.

The English edition of this valuable work has already been noticed in the *JOURNAL*,¹ and it only remains to welcome an American reprint as placing the work within the means of a larger number of readers. It is to be regretted, however, that this has been done by using the worn-out plates from England, and printing on very poor paper. This edition is only to be recommended to those who cannot afford to purchase Macmillan's publication.

LOCALIZATION OF CEREBRAL FUNCTIONS.

PROF. DAVID FERRIER, whose name is so intimately connected with the above subject, having been awarded the Marshall Hall prize, delivered recently before the Royal Medical and Chirurgical Society, at its first meeting this season, an especially lucid and interesting address upon the Progress of Knowledge in the Physiology and Pathology of the Nervous System. Many of our readers will remember the persecution before the courts to which Professor Ferrier was subjected by the anti-vivisectionists just after the meeting of the International Congress at London, on account of the experiments upon two monkeys, performed to prove to other physiologists his views in regard to cerebral localization. The address (reported in full in the *British Medical Journal*, October 27th) deals mainly with the gradual development and present position of this theory of localization of cerebral functions.

It opens with an acknowledgment of the Marshall Hall prize, and a eulogistic account of Marshall Hall's investigations into the nature and conditions of reflex action, a subject of such importance that its elimination would derationalize the better half of pathology and therapeutics. Not long prior to this investigator's study of the spinal cord and medulla oblongata, Flourens was engaged in his memorable researches on the physiology of the cerebral hemispheres. The doctrines of Hall, with modifications in detail, are those which still prevail, while those of Flourens, though having exercised an enormous influence on clinical medicine and pathology, are open to extensive criticism. Flourens held that the organ of the mind like the mind itself was one and indivisible, there being no differentiation of function, each part being capable of exercising every function pertaining to the whole. These views were once generally accepted, but some observers saw in certain clinical phenomena—as the occurrence of limited paralyses following limited lesions—facts inexplicable by this theory. Among these observers was numbered Dr. Hughlings Jackson, to whose keen perception Professor Ferrier accords the highest praise. Fritsch and Hitzig subsequently inaugurated a new era by showing the results of electrical irritation of different regions of the cerebral hemispheres.

The question of localization of cerebral functions was brought to a crisis at the International Congress of 1881. Goltz, as the champion of the Flourensian

system, while considering the cerebral cortex the seat of the higher intellectual functions, maintained the following views: (1.) Localized cerebral lesion cannot cause paralysis of any muscle or sense; (2.) Extensive removal of large portions of the cortex, however, causes defective perception; (3.) Destruction of the parietal regions causes permanent awkwardness and defective tactile sensibility; (4.) Removal of the occipital lobes causes greater dementia than that of the parietal lobes. The dog shown by Professor Goltz seemed in essential particulars to corroborate his theories. Against Goltz's dog were set the two famous monkeys, one showing total hemiplegia following destruction of the so-called motor tract, the other completely deaf from lesion of the superior temporo-sphenoidal convolution.

The seeming confusion resulting from contradictory results Ferrier points out should not lead us to ignore the logical results of experiment. Pigeons and frogs after removal of entire hemispheres behave much as before the operation. Dogs are absolutely powerless after the same injury. These facts illustrate the different degrees among different orders of animals in the part played by the cerebral hemispheres. If it is difficult with some animals to gauge the result of loss of whole hemispheres, it may well be difficult to show the effect of removal of a part. The fallacy in Goltz's experiment lay in the incomplete destruction of the motor area (afterward demonstrated on the brain), the remainder sufficing for incomplete motion.

Clinical researches in this connection are less reliable than physiological experimentation, but the experience of most clinical observers seems to favor the localization of cerebral functions.

Assuming then the general acceptance of the theory of localization, is this localization of centres a matter of accident, or is it dependent on structural peculiarities rendering each centre distinct from others; or is the brain-crust divided into fields each of which, though yielding some kind of produce, usually may, if need be, yield any other; or is it divided into fields each of which yields most of one kind of produce, but more or less of every sort? Each of these suppositions has its advocates. The indifferent or accidental theory is used by some to explain, by compensation, the recovery of motion after supposed complete destruction of the motor areas. This is probably fallacious reasoning, for complete destruction of certain portions of the cortex are followed not only by lasting paralysis, but also by secondary degeneration of the pyramidal tracts, a result following lesion of no other region of the cortex. The histological differences between the nerve cells of different regions of the brain, moreover, points to the same conclusions. Again as regards the region related to the organs of sense, destruction of certain cortical regions of both sides, for instance, causes blindness and atrophy of the optic nerves, establishing the final origin of the optic fibres, but the centres for the other senses do not rest as yet on so established a basis. The fact that the exact limits of the fields have not been determined is no argument against the theory of localization.

The following are the regions concerning which the least controversy exists: the convolutions bounding the fissure of Rolando have a special relation to the motor powers; the centres of hearing are in the superior temporo-sphenoidal convolution, and certain clinical observations favor a causal relationship between lesions of this region in the left hemisphere and word-deafness, though no case has been observed in man comparable to the deafness in the monkey produced by destruction of the auditory centres; the differences of opinion regarding the visual centres are mostly confined to the relations of certain cortical to certain retinal regions. It is probable that isolated affection of vision may be connected with cortical and sub-cortical lesions in the occipito-angular regions.

The centres of smell and taste are less definitely settled, but the greatest difference of opinion exists regarding the centres of muscular and general sensibility. Some place them in the motor tract; Ferrier holds them to be entirely distinct, occupying the sub-cortical region. Clinical research is of the utmost value in settling this question on account of its importance in the diagnosis of cerebral disturbance.

Tested by the standard of practical utility, the benefits of this doctrine of cerebral localization have been absorbed into medical science itself. It has sharpened clinical vision; it has given a decision to clinical and pathological descriptions; it has cleared our conceptions as to the significance of numerous symptoms, and is every day bringing us nearer to that which Virchow has termed the goal of modern science, namely, localization of disease. There are also already signs that we are within measurable distance of the successful treatment by surgery of some of the most distressing and otherwise hopeless forms of intracranial disease, which will vie with the achievements of abdominal surgery. There is no more reason, with stringent antiseptic precautions, for shrinking from opening the cranial than the abdominal cavity. Apart from secondary inflammation and its consequences, which can be absolutely prevented, there is no risk to life from even extensive destruction of the cerebral hemispheres. The records of our daily experience of disease and injury of the brain show that considerable portions of the brain substance may be destroyed without great danger to mental stability, and with the exception of certain functions, arrogated by the left hemisphere, we have practically for mental purposes two brains. Paralysis, as well as other complications incidental to all surgical procedures, may ensue after cerebral operations, but the choice often is not between this and some other treatment, but between these risks and certain death,—a choice over which few would hesitate.

THE CHOLERA GERM.

It is already a number of weeks since the unofficial announcement by cable of the discovery of the cholera germ by Koch and his associates in Egypt, whither they were sent by the German government to study the disease. Such an announcement coming from

Koch himself, whose accuracy and prudence are now well known, would command attention, but as a mere news item it scarcely deserved serious consideration. Koch's own report upon his observations is now at hand, and exhibits his characteristic caution. It seems that cholera was already declining in Alexandria, where the commission pursued its studies, when it arrived there; only twelve cases could therefore be investigated during the disease, and ten examined after death. The only distinctive result reached was the verification of the constant presence in the intestinal walls, and principally in the walls of the lower part of the small intestine, of a micro-organism of the bacillus type, which had previously been observed by Koch in specimens from cholera victims sent him from India, and which he had hitherto thought might be attributable to putrefactive changes. These micro-organisms were isolated and propagated in pure cultures, according to Koch's now well known method. The next essential link in the chain of proof that these constitute the specific germ of cholera is still wanting. Koch failed to reproduce cholera by inoculation of the lower animals with his cultures. This failure may be owing to an immunity of the animals to the disease; it may be owing to the same attenuation of the virus which was reflected in the declining disease in Alexandria; or it may very well be that this bacillus is after all not the specific microbion wanted. Koch's mind is of too scientific a cast not to appreciate these alternatives, and he has shown himself too candid not to announce them.

The commission, with the consent of the German government, has gone on to Bombay to pursue its investigations under more favorable circumstances, and with ample material. In the mean time the profession and the public can afford to await the official announcement of the result of its labors.

"REGULARS" AND "IRREGULARS" OF THE DAILY PRESS.

THE little excitement among our esteemed daily contemporaries in Boston, which manifested itself recently upon the publication of the enemy's campaign documents, in the form of advertisement, by one of their number toward the close of the recent exciting political campaign in this State, caused us, we may confess, some little amusement. We read the mutual criminations, recriminations, and definitions of position and propriety, and tried, by reminding ourselves that perhaps all men are not equally fitted to decide every question, to abstain from immediately settling the merits of the controversy off-hand. But it did occur to us that our neighbor's ox was now being gored, and the process seemed to evoke not indistinct cries of "regular" and "irregular," "code" and "no code," tory and liberal. At the same time the suspicion presented itself that very likely a contemporary was being persecuted, and whether as descending from the Puritan we ought not without more ado to give him our countenance and support.

Why should not industrious, law-abiding, intelligent newspapers earn their livelihood in their own fashion, and cater to the tastes of an appreciative public in the way of advertisements, or anything else, without this antiquated jargon and mummary about "principles," and "standards," and "regularity," and unwritten "ethical codes," etc., etc.? Cannot a newspaper manage its business in its own fashion, even if striving to increase its influence and profit by an uncalculated aberration, without these efforts to prejudice the public against it, and these intimidating prophecies of an enormous loss of circulation? Cannot a Massachusetts public be trusted to know what it wants to pay for?

The time is not far off when even esteemed daily contemporaries will be emancipated from all this sort of old-fashioned nonsense, which we are sorry to see encouraged by so large and respectable a part of them. People in this community were not born to be slaves, and they won't tolerate persecution of anybody or anything.

THE REMOVAL OF THE REMAINS OF WILLIAM HARVEY.

ON October 18th an exceedingly interesting ceremony took place at Hempstead, England, a village some fifty miles from London, on the occasion of the removal of the remains of the illustrious Harvey to a more secure and appropriate resting-place. Harvey died at the age of eighty, in June, 1657, and was buried in a vault with other members of his family under the "Harvey chapel," which was erected by a brother of William. The coffin was of lead, and bore an inscription which is still legible. The case itself, however, was in bad condition, and contained water most of the time; the lid had fallen in, and it is supposed that even the skeleton now no longer remains. Even in these damp and repulsive surroundings many pilgrims had found their way to the shrine, and the adjacent coffins were many of them flattened out by those who had stood upon them in order to decipher the inscription. Several efforts had been made to place the remains in a more worthy position, but had not been successful. Dr. B. W. Richardson had moved in the matter of having the body transferred to Westminster Abbey, and Dean Stanley wished to place it beside the remains of Hunter or Livingstone, but the illness and death of the dean put a stop to this undertaking. Last year the fall of a portion of the edifice again suggested that something should be done, and Dr. Richardson found that though the coffin had not been buried in the debris, it was fast dropping to pieces. On his report of these facts to the Royal College of Physicians, a committee was appointed to investigate the subject. This committee advised that the remains be kept at Hempstead, but that they be removed to the chapel above the vault. The necessary permission was obtained, and a sarcophagus of Carrara marble erected, the floor of the chapel having been strengthened for that purpose.

The following inscription was placed at the head of the sarcophagus:—

WILLIAM HARVEY
BORN 1578
DIED 1657

The following was engraved on one side:—

The remains of William Harvey
Discoverer of the Circulation of the Blood
were reverentially placed in this Sarcophagus by
the Royal College of Physicians of London
in the year 1883.

A leaden case was also prepared, in which might be placed the edition of the works of Harvey published in Latin by the Royal College of Physicians of London in 1766, and edited by Drs. Akenside and Lawrence. On one side of this was engraved:—

GULIELMI HARVEII
OPERA OMNIA
EDITA
MDCCLXVI

On the other side was inscribed:—

The complete works of William Harvey,
deposited October 18th, 1883.

A memorial bottle, hermetically closed, was also prepared for the occasion, and wrapped in lead. In the bottle was placed a memorial, engrossed on vellum. The leaden case inclosing the bottle had inscribed upon it:—

SCROLL.

Deposited October 18th, 1883.

The following is a copy of the memorial itself:—

"The body of William Harvey lapt in lead simply soldered was laid without shell or enclosure of any kind in the Harvey Vault of this Church of Hempstead, Essex, in June, 1657.

"In the course of time the lead enclosing the remains was from exposure and natural decay so seriously damaged as to endanger its preservation, rendering some repair of it the duty of those interested in the memory of the illustrious discoverer of the Circulation of the Blood.

"The Royal College of Physicians, of which corporate body Harvey was a munificent Benefactor, and which by his favour is the possessor in perpetuity of his patrimonial Estate at Burmarsh, Kent, did in the years 1882-83 by permission of the Representatives of the Harvey family undertake that duty.

"In accordance with this determination the leaden mortuary chest containing the remains of Harvey was repaired and as far as possible restored to its original state, and on this 18th day of October, 1883, in the presence of four Representatives of the Harvey family and of the President, all the office-bearers and many other Fellows of the College of Physicians (whose names are herunto appended) was reverently translated from the Harvey Vault to this Sarcophagus raised by the College for its reception and preservation."

This memorial was signed by four representatives of the Harvey family and by the committee, which included some of the most illustrious names in English medicine.

The ceremony of the recommitment took place on St. Luke's day, and a special train conveyed the visitors down from London. The *British Medical Journal* thus describes the affair:—

"Dr. Allchin, the assistant registrar of the college, had gone before to Hempstead, to make the final arrangements for the carrying out of the programme of the day. Upon arrival at Hempstead, where a large number of persons were assembled, the President and the officials of the college immediately assumed their robes of office, and a visit was made to the vault to view the chamber and Harvey's shell with the other coffins lying there. Harvey's leaden coffin was then raised to the church-yard up an inclined plane made by

placing boards over the flight of steps. The eight Fellows of the college who acted as bearers, Sir Risdon Bennett, Drs. Owen Rees, Quain, Sieveking, Richardson, Shepherd, Duckworth, and Moore, then ranged themselves on either side of the coffin, and carried it through the church-yard, and up the nave and aisle, into the Harvey Chapel. Following the remains was a procession which included the four representatives of the Harvey family above named, the president of the college, carrying the silver emblem of his office; the college officers in their gowns; and the Fellows of the college mentioned above, conspicuous amongst whom were Drs. Acland and Paget, the Regius Professors of Medicine, in their scarlet robes; besides these gentlemen were Dr. Broadbent, Dr. Hubert Airy, Mr. George Eastes, and Mr. Stear. The remains of Harvey were then lowered into the sarcophagus, and Sir William Jenner placed the metal case containing the scroll sealed in a glass bottle, and the metal box containing the copy of Harvey's works, beside the leaden coffin in the interior of the sarcophagus. Thus within the last few years full honor has been done by Englishmen to the memory of Harvey. A noble statue, subscribed for by all classes of people has been erected in his birthplace, Folkestone, Kent, and now the Fellows of his own loved College of Physicians have, with their own hands, placed his remains in a tomb which will for centuries demonstrate to the world the admiration which, in 1883, they entertained for the signal services rendered to mankind by Harvey."

This ceremony, conducted with all that pomp and circumstance to which our English brethren cling so tenaciously in many matters touching their every-day life, but which is nowhere more religiously observed than in the formal proceedings of the College of Physicians, must have suggested a marked contrast to the spirit which actuated Harvey himself, when, in opposition to the crude physiological and theological fancies of his time, he dared boldly to invade the "spiritual" organ itself, and search curiously into its working in the living animal. Vivisection had far more excuse for being resisted in the seventeenth century than in the nineteenth, when two centuries of experience of the beneficent results of experimental research in the relief of suffering, by something like a rational idea of some of the vital processes, have plead its cause.

The maintenance of old forms, so far as it does not interfere with the work of to-day, is certainly defensible, and to one with a sense of the picturesque, quite justifiable. But the preservation of old-time prejudices, which Harvey was able in some measure to overcome two hundred years ago, to the obstruction of the scientific advancement of the world, is without excuse.

MEDICAL NOTES.

— The total number of medical students entering the London schools for the full curriculum this fall is 605. This number is seventeen below that of last year. St. Bartholomew's, as before, heads the list.

NEW YORK.

— At a meeting of the Medico-Legal Society held November 7th a resolution, proposed by Dr. R. J. O'Sullivan, was passed, requesting the Committee on School Hygiene to tender its co-operation to General Shaler, President of the Board of Health, in his efforts to improve the sanitary condition of the public schools. The officers of the Health Department have recently made a systematic inspection of the school-houses of the city, and reported that in many of them the air is poisoned by bad drainage, defective plumbing, or insufficient ventilation, or by all combined. In speaking upon the resolution Dr. A. W. Bell, editor of the *Sanitarian*, said that he hoped the movement would not end in smoke, as had been the case before. He thought the Board of Education was, perhaps, born in a state of incapacity to estimate the sanitary needs of the schools, and it was impossible for it to overcome this congenital difficulty. An examination some time ago to test the purity of school-room air had resulted in the discovery that there was more poisonous carbonic acid gas habitually present in them than in the prisons of the city. The Board of Education had passed a resolution requiring that there should be an average space of seventy cubic feet of air for each pupil, but this had never been carried out, not more than fifty cubic feet being at present the allowance in many of the schools. He believed that out of sixty thousand children three thousand had died during the last two years, smothered to death. Having called attention to the especially bad condition of one of the school-houses, he stated that the schools in Brooklyn were equally faulty. On motion of Mr. Hull a committee was appointed to report concerning the condition of the Brooklyn schools.

Prof. Charles A. Doremus then read a report of a toxicological examination for arsenic prepared by Dr. John J. Reese, professor of toxicology in the University of Pennsylvania, and incidentally alluded to the importance of guarding against the addition, by coroners or others, of alcohol as a preservative, or any other substance whatever, to parts to be submitted to the chemist for analysis, on account of the danger of the analysis being invalidated thereby.

— The Society of Medical Jurisprudence and State Medicine met at the hall of the Academy of Medicine on Thursday evening, November 8th, when a paper on Sunstroke was read by Dr. Charles A. Leale, which was discussed by Drs. C. S. Wood and E. C. Spitzka. The annual election of officers took place on the same evening, and resulted as follows: President, William Barnes, Esq.; Vice-President, Dr. E. J. Bermingham; Secretary, Dr. Nathan E. Bull.

— The coroner's jury which for some time past has been investigating the death of Mabel Curry, an infant eleven months old, which occurred at the Mount Vernon branch of the New York Infant Asylum, has just rendered the following verdict severely censuring the female physician in charge, and arraigning the management of the institution:—

"We find that Mabel Curry's death was due to a teaspoonful of ammonia administered by night nurse

Anna Howland, by mistake. We further find that Dr. Caroline G. Marr, the resident physician of the asylum, was promptly notified of the fact that the ammonia had been administered to the child, but that she neglected to give any antidote therefor or to take any measures to counteract the effect of said ammonia. At the time the ammonia was administered the child was not considered dangerously ill, and in our opinion her death was caused by the inexcusable, culpable, and criminal negligence of Dr. Caroline G. Marr. We also find that Dr. Caroline G. Marr certified that the child died from measles and bronchitis, whereas, in fact, the child died from the effects of the ammonia; of which, as we believe, Dr. Marr had full knowledge. We find, also, that from about August 1st to about October 1st an epidemic of measles, whooping-cough, and dysentery was raging in the asylum, with great mortality among the inmates, and that during that time Dr. Marr was the only regular physician in attendance. In our opinion the said Dr. Caroline G. Marr was not competent, either professionally or physically, to perform properly the duties which then devolved upon her, and many lives were sacrificed that might have been saved had proper and sufficient medical attendance been provided by the management of the asylum. We therefore believe it to be our duty to condemn and censure the management of said asylum for leaving the same during the epidemic unprovided with proper medical attendance."

During the inquest the night nurse, Anna Howland, testified that she had been appointed to that position by Dr. Marr, although she had never received any training qualifying her for its duties. She gave the aqua ammonia to the child in mistake for solution of quinine, and when informed of the occurrence Dr. Marr said that the ammonia would not do any harm. No medicine was given the child from the time it took the ammonia up to the time of its death, which occurred about twenty-four hours afterward.

Experts testified that a teaspoonful of aqua ammonia should be considered a fatal dose if administered to a child eleven months old. The town clerk of East Chester produced the certificate given by Dr. Marr, assigning measles and bronchitis as the causes of Mabel Curry's death, and testified that during the months of August, September, and the first half of October there were received sixty-eight certificates of death from the asylum at Mount Vernon. Three of the attendants at the asylum testified during the inquest that they have frequently seen Dr. Marr under the influence of liquor, and all three have been summarily dismissed from the institution in consequence.

It is intimated that the coroner, on account of the nature of the jury's verdict, will probably issue a warrant for the arrest of Dr. Marr on a charge of manslaughter.

— Dr. John McNeil, an old and highly respected practitioner of Jersey City, and one of the commissioners of the County Board of Health, died on the 9th of November. During the war he was surgeon of the Twenty-First Regiment of New Jersey Volunteers.

Correspondence.

LETTER FROM LONDON.

MR. LISTER ON FRACTURE OF THE PATELLA.

MR. EDITOR, — On the evening of Monday, October 29th, was inaugurated the one hundred and eleventh session of the Medical Society of London, the President, Sir Joseph Fayrer, in the chair.

After the usual balloting for members — one of our own countrymen, Professor Yandell, of Louisville, Ky., being elected to honorary fellowship — the President read his opening address, in which he stated that the present season bids fair to be of unusual interest and enjoyment, as already a large number of Fellows from all parts of England — among them Sir Andrew Clark — have signified their intention of presenting papers to the Society. The President suggested that a communication on *albuminuria* just at this time would be of great interest and importance.

After a short sketch of the Society's history, and an appeal to the members for still greater activity, the President closed his address with a few complimentary remarks to Mr. Lister, who was then introduced as the reader for the evening. The *Lancet* for November 2d will contain a full report of Mr. Lister's paper, which was on the Silver Wire Treatment of Transverse Fracture of the Patella, and of which the following is a short abstract: —

In 1873 Mr. Lister suggested to his house-surgeon that a suitable treatment for fractures of the olecranon and patella would be to wire the fragments of the bone together, as is done in certain cases of ununited fracture of the long bones.

Some time after this a case of fractured olecranon presented itself at the Edinburgh Infirmary, where Mr. Lister then was, and was operated upon. After cutting down to the bone the edges of the pieces were pared, a hole bored through the centre of each with a bradawl and a needle, and the two pieces brought together with silver wire, which was fastened by a full twist, and the ends left projecting from the wound. In due time complete union of the bone was found to have taken place; the wire was removed, and, the external wound healing rapidly, the patient soon regained the full use of his arm, and was able to return to his work of blacksmithing. One or two other like cases, equally favorable, were also reported. The wire used for the olecranon was of silver, and one four hundredth of an inch in diameter. Wire for the long bones should have a diameter of one tenth inch.

The reader then took up the subject of his paper, reporting seven cases of fractured patella treated by the wiring method, and presented six of the cases to the Society, the seventh case having been lost sight of soon after leaving the hospital.

In all these six cases perfect bony union of the fractured part was found to have taken place. The cases had been treated at the King's College Hospital within the past few years, the last one having been operated upon in the spring of the present year.

The *modus operandi* of the operation is so simple that, according to Mr. Lister, a first year student ought to be able to perform it as well as the experienced surgeon. The fractured bone is laid bare by a two-inch long incision in the median line. A hole is now bored with a bradawl in the centre of the margin of each

fragment of bone. This hole should not extend through the cartilage on the under side of the patella, but should run at an angle so as to come out on the fractured surface just above the cartilage. If it is a case of ununited fracture of several weeks' or months' standing, the edges of the fracture must be pared to remove all ligamentous tissue. The joint is then thoroughly cleansed of blood clots and fluid, and a drainage tube inserted. To make room for the tube, a perforation from the wound is made with the dressing forceps before cleaning the joint, — through the tissues to the exterior (side) of the knee, — the skin over the point of the forceps being cut through from the outside. The blades of the forceps are then opened to dilate the canal, and the drainage tube inserted in the space thus formed. Silver wire is now run through the holes in the fractured patella, and the fragments drawn into close apposition. A complete twist is given to the wire to hold it in place, and the ends allowed to project through the external wound, which is "put up" in antiseptic dressings, and the leg placed in a long splint. In every case, as stated above, bony union, with complete restoration of the power of the leg, was the result. In the last two or three cases, instead of leaving the ends of the wire sticking through the wound, the removal of which required a second operation of cutting through the recently formed cicatrix, etc., the wire after "two half twists," to use Mr. Lister's own words, was cut off short, and the ends hammered down onto the patella. This method has several advantages. It holds the fragments more firmly together, and admits of a much earlier use of the leg than could otherwise be allowed, and it obviates a second operation.

In one case, after the lapse of many months, the wire could not be detected; while in another it was just discernible to the touch, the skin moving freely over it. It is thus proved that the presence of the wire causes no further inconvenience. In the case of a man over sixty years of age, who had fallen from an omnibus and received a comminuted fracture of the patella, two pieces of bone from the lower fragment — one the size of a filbert, the other somewhat smaller — were found loose in the joint and removed. The very small remaining fragment, with the ligamentum patellæ, was then wired to the upper fragment, the result being a perfect union, with evidently new osseous growth, as the patella now appears quite normal. This was done in the early part of the present year, and the man has not yet wholly recovered complete use of the leg, although he walks without a limp, and says that the leg grows stronger every day. In another case the patient is a stamper, and works the weight (sixty pounds) with the injured leg, suffering no inconvenience.

It was interesting to notice the temperature charts which were shown. In no case was there febrile reaction; in one or two the temperature going up slightly after the operation, but immediately sinking and remaining normal. Mr. Lister believes that the operation should be done in recent fractures, and not put off until all other means have failed, — as in cases of long standing the bone becomes thinned by absorption, and there is less chance for a firm bony union from the operation. Recent fractures should not be treated at once, but should remain quiet until the inflammation has subsided. In one case this occurred as early as the third day; in another on the seventh. Mr. Lister considers this operation not only justifiable,

but, under certain conditions, obligatory on the part of the surgeon. These conditions are strict antiseptia. If the surgeon can with a clear conscience say that no septic material can enter the wound, it is his duty to operate. Mr. Lister's remarks on antiseptic treatment being cheered by the members, he thanked them, with evident pleasure, saying that such remarks a few years ago would have been received very differently. The hour being late, after a vote of thanks to the reader, the meeting was adjourned,—the discussion of the paper being postponed until the following Monday, when Mr. Lister is expected to continue his remarks on Antiseptic Surgery. W. P. MANTON.

Miscellany.

OBITUARY. ROBERT DWYER JOYCE, M. D.

INTELLIGENCE has been received of the death from phthisis of Dr. Joyce, which occurred at the residence of his brother in Dublin, October 23d, whither he went but a few months ago from this city. Dr. Joyce was born in Limerick County, Ireland, and received his rudimentary education at the ordinary country English and classical school near his father's place. He was subsequently sent to Dublin to complete his education, and afterward studied medicine at the

Queen's University, where he received his degree, and was then appointed Professor of English Literature in the Preparatory College of the Catholic University, Dublin. He practiced his profession for several years in Dublin with success, and in the intervals of his medical work contributed freely in prose and verse to many Irish periodicals. His allegiance to the cause of his native land was always very strong, and his writings breathe an intensely patriotic spirit. A volume of Ballads, Romances, and Songs earned for him from an English critic the title of the "Scott of Ireland." He gave hearty assistance to the Fenian movement, and was one of the most earnest writers upon the staff of its official organ.

In 1866 Dr. Joyce sailed for this country, and took up residence in this city, where he has since practiced his profession with success. His muse was employed for several years, during the intervals in his professional life, with ballads, songs, and sketches brimful of patriotism, which appeared in the *Pilot* and other Irish-American journals. In 1872 an edition of his poems was published which was well received by the critics. Dr. Joyce's crowning work, however, was *Dierdré*, an epic which appeared anonymously as one of the "No Name" series, and which was the cause of much speculation regarding its authorship. This and *Blanid*, which appeared later, earned their writer an enviable reputation as a poet.

Deaths reported 2062 (no reports from Brooklyn, New Orleans, and Charleston): under five years of age, 701: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 450, consumption 319, lung diseases 197, diphtheria and croup 184, typhoid fever 75, diarrhoeal diseases 74, scarlet fever 43, malarial fevers 30, whooping-cough 14, cerebro-spinal meningitis nine, measles six, puerperal fever six, erysipelas five, small-pox four. From *scarlet fever*, Philadelphia 12, Chicago 10, New York eight, Boston four, Baltimore, Milwaukee, and Lowell two each, Cincinnati, District of Columbia, and Pittsburg one each. From *malarial fevers*, New York 12, Baltimore 10, St. Louis five, Chicago two, Philadelphia one. From *whooping-cough*, New York five, Boston three, Baltimore and District of Columbia two each, St. Louis and Cambridge one each. From *cerebro-spinal meningitis*, Cincinnati four, New York three, Chicago and Fall River one each. From *measles*, New York four, Baltimore and District of Columbia one each. From *puerperal fever*, Chicago three, Boston, Baltimore, Cincinnati, and Fall River one each. From *erysipelas*, Boston three, New York and Philadelphia one each. From *small-pox*, Philadelphia four.

In the 29 cities and towns of Massachusetts, with an estimated population of 1,035,778 (estimated population of the State 1,922,530), the total death-rate for the week was 19.08 against 18.69 and 19.34 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending October 20th, the death-rate was 19.6. Deaths reported 3240: acute dis-

eases of the respiratory organs (London) 252, scarlet fever 126, diarrhoea 122, fever 58, measles 54, whooping-cough 40, diphtheria 37, small-pox (Birmingham four, Sunderland one) five. The death-rates ranged from 11.1 in Norwich to 29.3 at Newcastle-on-Tyne; Bristol 15; Sheffield 17.8; Sunderland 18.1; London 18.6; Bradford 18.9; Birmingham 26; Leeds 26.8. In Edinburgh 16.4; Glasgow 22.1; Dublin 23.3.

For the week ending October 13th, in 168 German cities and towns, with an estimated population of 8,557,837, the death rate was 23. Deaths reported 3786; under five years of age, 1865; consumption 475, diphtheria and croup 289, lung diseases 278, diarrhoeal diseases 223, scarlet fever 141, measles and röteln 57, whooping-cough 54, typhoid fever 49, puerperal fever 27, small-pox (Erlangen, one) one. The death-rates ranged from 11.5 in Mainz to 34.6 in Königsberg; Breslau 25.1; Munich 29.9; Dresden 24; Berlin 24.7; Leipzig 17.8; Hamburg 20.8; Cologne 21.3; Frankfurt a. M. 17.4; Metz 23.1.

For the week ending October 20th, in the Swiss towns, there were 22 deaths from lung diseases, consumption 17, diarrhoeal diseases 13, diphtheria and croup two, whooping-cough two, puerperal fever two, erysipelas one, typhoid fever one. The death-rates were, at Geneva 11.3; Zurich 20; Basle 11.9; Berne 22.6.

The meteorological record for the week ending November 3d, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

Date.	Barometer.	Thermometer.				Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM NOVEMBER 2, 1883, TO NOVEMBER 9, 1883.

BACHE, DALLAS, major and surgeon. Paragraph 1, S. O. 238, A. G. O., October 18, 1883, assigning him to duty at Willer's Point, New York, revoked. Paragraph 2, S. O. 252, A. G. O., November 3, 1883.

STERNBERG, GEORGE M., major and surgeon. Leave of absence granted October 4, 1883, extended one month. Paragraph 4, S. O. 255, A. G. O., November 7, 1883.

VICKERY, R. S., major and surgeon. Assigned to duty at Fort Townsend, W. T. Paragraph 3, S. O. 149, Department of the Columbia, October 29, 1883.

WOLVERTON, WILLIAM D., major and surgeon. Granted leave of absence for one month. Paragraph 6, S. O. 201, Department of the East, October 24, 1883.

MERRILL, J. C., captain and assistant surgeon. Granted leave of absence for one month. Paragraph 7, S. O. 201, Department of the East, October 24, 1883.

PATZKI, J. H., captain and assistant surgeon. Granted leave of absence for three months, on surgeon's certificate of disability. Paragraph 6, S. O. 254, A. G. O., November 6, 1883.

OWEN, W. O., first lieutenant and assistant surgeon. Relieved from duty at Vancouver Barracks, W. T., and assigned to duty at Fort Stevens, Oregon. Paragraph 2, S. O. 148, Department of the Columbia, October 26, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING NOVEMBER 3, 1883.

THE orders of Medical Inspector A. C. GORGAS to the Naval Hospital, Mare Island, Cal., revoked, and to remain at Naval Hospital, Chelsea, Mass.

ROBINSON, SOMERSET, medical inspector, to the Naval Hospital, Mare Island, Cal.

DEARBORNE, F. M., surgeon, to appear before the Retiring Board, November 5th.

GIHON, A. L., medical director, and A. HUDSON, medical inspector, to represent the Navy at the meeting of the American Public Health Association at Detroit, Mich., November 13th.

SUFFOLK DISTRICT MEDICAL SOCIETY. *Section for Obstetrics and Gynecology.*—There will be a meeting of the Section at 19 Boylston Place, on Wednesday evening, November 21st, at 8 o'clock. Dr. Swift will report a case of Face Presentation.
J. B. SWIFT, Secretary.

DEATHS.—Died at Dublin, Ireland, October 23, 1883, Robert Dwyer Joyce, M. D., M. M. S. S., late of Boston.
At Milford, Mass., November 7, 1883, Joseph Allen Fay, M. D., M. M. S. S., aged thirty-nine years.

Lectures.

ON THE TREATMENT OF DIABETES.

A CLINICAL LECTURE BY PROFESSOR DUJARDIN-REAUMETZ,

Member of the Academy of Medicine, Physician to the Hôpital St. Antoine, etc., Paris, France.

GENTLEMEN, — The dietetic treatment of diabetes deserves the first place. Ever since John Rollo at the end of the last century first called attention to the influence of foods in the production of glycosuria, all authorities have felt the obligation to regulate rigorously the diet of diabetic patients. At their head is Bouchardat; after him I will mention especially Seegen, a German writer, and Cantani, an Italian, and what I have now to offer respecting the hygienic régime of this affection will be based on a careful study of the contributions of these three men.¹

The hygienic treatment is founded on the endeavor, as far as possible, to exclude from the food all substances capable of forming glucose. This glucose may be derived from sugar in the ingesta, or from starch which has undergone conversion in the alimentary canal. These glycogenous principles, then, should be suppressed. All this, however, though simple in theory, is difficult in practice.

I told you in a former lecture, when on the subject of digestion, that an adult man loses by day twenty grammes of nitrogen and 310 grammes of carbon, and that in order to avoid emaciation he must obtain in his food this quantity of nitrogen and of carbon; it is well always to have these figures before you when you wish to lay down dietetic rules for your diabetic patients. The 310 grammes of carbon are furnished by sweets, feculents, and fats, and the suppression of the first two of these alimentary substances must considerably modify the conditions of alimentation. For, in order to suffice for this combustion of 310 grammes of carbon, if a man eats nothing but meat, he must consume two kilogrammes, so that a diabetic patient confined to a diet exclusively of animal food must be made to eat about four pounds a day! This enormous amount of meat is not without its inconveniences; by the quantity of nitrogenous material not utilized it augments waste-production, and provokes lithæmia; it moreover fatigues unduly the functions of certain portions of the digestive tube.²

Therefore Cantani, while suppressing entirely sugar and starch, has replaced these principles by fat, establishing thus what he calls *adipo-albuminous* diet; but as sometimes these oleaginous substances, which ought to be absorbed in great quantity, are of difficult digestion for certain stomachs, he first submits them artificially to the action of the pancreas, and administers to his patients *pancreatized fats*.

The régime of Cantani is difficult to follow in all its rigor; there are so few who can for a series of months subsist on meat and fat alone, for Cantani aims to have

this adipo-albuminous diet continued till the complete disappearance of sugar from the urine.⁴

Hence the dietetic régime of Bouchardat is more generally adopted; the principal characteristics of this alimentary system consist in the substitution of gluten for starch, and in the employ of gluten-bread.⁵

of Fat in Diabetes, etc., Deut. Arch. f. klin. Medicin, Bd. xxv., Hft. 4 and 5, p. 470, 1880.)

⁴ This is the alimentary régime of Cantani: —

Broths. Made with any sort of meat.

Beef. Muscle, brains, tongue, etc.

Veal. The muscle, all the internal organs, brain, sweet-bread, lungs, kidneys, but not the liver.

Mutton. The same as above.

Fowl and game of all kinds. Fish, frogs, and crustaceans.

Salt or canned meats or fish, but in moderation.

All the above may be either boiled, roasted, broiled, or fried in fat, and salted to the taste. They may be seasoned, but no sugar or starch must enter into the composition of the seasoning ingredients; also no wine, vinegar, butter, or lime juice. Olive oil and animal fats may be used freely, and dilute acetic acid may be substituted for vinegar, and citric acid for lime juice.

The quantity of food should be about 600 grammes a day, of cooked meat, and more if the scales show that the patient continues to emaciate.

In cases where denutrition is very pronounced, in very lean patients, sixty to two hundred grammes of *pancreatized fat* are given daily; this is prepared as follows: Cut into small pieces the fresh pancreas of a beef creature or sheep, intimately blend with it a small quantity of fat, and leave it for three hours or so submitted to this artificial digestion, then cook slightly.

Drinks. Water, pure, or artificial seltzer water, to which from ten to thirty grammes daily of rectified spirits may be added, and some aromatic waters (fennel, cannella, balm, mint, orange) if desired.

If, after a month's trial, this régime does not cause the glycosuria to disappear, it will be best to make the patient fast twenty-four hours, taking nothing but water and some rich broth. Then the above regimen is resumed, but in half the quantity; little by little it is increased till the normal quantity is attained. But if the glycosuria reappears, another day of fasting, then the half diet again; which is not to be increased, unless the scales show that the patient is losing flesh.

In very recent cases, or cases of little gravity, eggs may be permitted, the liver of animals, cod-liver oil (two to four ounces a day), and shell fishes, such as oysters, snails, and clams. A little old red wine (Bordeaux wine is the best), a little tea or coffee without sugar.

Exercise in the open air, gymnastics, muscular labor; this régime should be rigorously persisted in for two months at least in light and recent cases; for three, six, and even nine months in the severer cases.

The return to saccharine and amylaceous articles of diet should be gradual, in accordance with the indications given below.

The following aliments may be permitted to a diabetic patient who for two months at least has had no sugar in his urine: —

Gradual return to a mixed diet. Spinach, chicory, endives, watercresses, lettuce, dandelion, corn salad, olives, etc.

A little later. Chards, white beets, celery, artichokes, leeks, truffles, mushrooms.

A month after. Sweet almonds, nuts, pistachios, a little red wine.

Still later. Gooseberries, peaches, apples, and other fresh ripe fruits, fresh cheese, butter, etc. Little by little vegetables abounding in starch, such as potatoes, are allowed.

During the entire duration of this return to a mixed diet the quantity of these permitted aliments to be very moderate, and, on the least reappearance of glycosuria, the meat régime must be resumed in all its rigor. As for cane sugar, it must be absolutely prohibited at all times. (Cantani, Du Diabète et son Traitement, traduction Charvet, 1880.)

⁵ The following, epitomized, are the general precepts of Bouchardat to diabetic patients: —

Eat moderately and slowly, chewing your food thoroughly.

As long as the quantity of urine of twenty-four hours is above a litre and a half (fifty ounces), drink as little as possible.

A minimum of liquid food, such as broth, soup, *consommé*.

Sip your liquids, rather than *drink*; small quantities always to be the rule. The sense of thirst can often be assuaged by rinsing the mouth with ice water, or by chewing a little roasted coffee or chocolate nuts.

Two meals a day; one at ten A. M., the other at six P. M. Instead of taking a nap after meals, take a short walk in the open air.

Do not go to bed till at least four hours after the last meal.

Abstain from tobacco as far as possible. Abstain from feculents and sugar in general. In particular, avoid all sweet food, bread of

all cereals, pastries, rice, maize, and other feculent grains, potatoes, arrow-root, sago, tapioca, etc., all such farinaceous preparations as macaroni, vermicelli, cracked wheat, beans, peas, lentils, chestnuts, and other nuts, turnips, radishes, carrots, beets, and other saccharine or feculent roots, all fruits, and especially the sweet fruits, such as plums, prunes, apricots, raisins (either fresh or dried),

¹ Continued from page 461.

² Rollo, on Diabetes Mellitus, London, 1790. Seegen, on the Diet Cure of Diabetes (Wien. med. Woch., 1873). Bouchardat, du Diabète-Sucré, Paris, 1875. Cantani, on the Diet Treatment of Diabetes, 1876.

³ Bloch has studied the action of régime on diabetic patients. He has shown that animal food is capable of diminishing the proportion of sugar in the urine without causing it to disappear; fasting has the same effect; and, moreover, the absorption of fats is very active in diabetic patients. So, according to him, a flesh diet, while causing sugar to disappear, hastens denutrition. (Bloch, Absorption

This question of bread is of great importance. Habituated from their infancy to this sort of aliment, bread is to some persons quite indispensable, so that it is hardly possible for them to make a meal without it. This with our diabetic patients is a feeling which ought to be overcome. Insufficient alimentation is with these patients one of the gravest evils. You may by severe diet-restrictions cause sugar to disappear from the urine, but it is at the expense of the well-being of the entire organism. So your efforts ought to be directed toward instituting a regimen which, while excluding starchy and saccharine elements, may satisfy in a certain measure the taste and appetite of your patients.

Gluten bread and gluten cakes have been given to diabetic persons. Unhappily the mode of preparation of this kind of bread is not always what it should be, and when these culinary products have been analyzed, as they have been recently by Boussingault and Mayet, it is seen that they contain from ten to forty per cent. of starch. Therefore there has been a disposition to substitute for bread of gluten badly prepared, bran bread, as recommended by Camplin, or bread or biscuits of sweet almonds, as Kronser and Pavy have advised, or bread made of parched flour after Dannecy's formula, or the bread which Dahmen counsels.¹

You would do well, gentlemen, to use all these products, as well as the crust of ordinary bread and stale bread, for it is not so much the amount of starch and sugar contained in bread that is to be taken into account as the quantity which the patient eats. The dry gluten bread recommended by Bouchardat and the almond cakes and the bran cakes being generally hard and firm, the patient, whose gums are almost always affected with that diabetic gingivitis which loosens the teeth, is able to eat but a small quantity, and this is the reason why I prefer bread crust or hard, stale bread, for the patient can eat but a little of it. Add, moreover, that gluten bread is much less agreeable to the palate than ordinary bread, and that this circum-

stance contributes to minimize the quantity of this kind of food taken with meals.

stances contributes to minimize the quantity of this kind of food taken with meals.

Pastries ought absolutely to be prohibited. Do not forget, in referring to the interesting analyses of Boussingault and Mayet, that there is an alimentary preparation, *échaudé* or *simnel*, which has as much starch as ordinary bread (the first containing fifty-three and the second fifty-five per cent.), and this should be proscribed. Other kinds, as *brioche*, may be permitted as including no more starch than the gluten biscuits, or about forty per cent.

These same analyses enable us to establish a diabetic régime from the point of view of feculents; potatoes, turnips, and rice contain relatively a small proportion of sugar (seven to eight per cent.), while gluten bread has 27.70 per cent; hence the former are less objectionable in this respect than the latter. But I repeat, all depends on the quantity of these aliments taken by the patient. If the diabetic eats largely of potatoes, notwithstanding the small quantity of sugar in them, he will obtain the same amount of sugar as if he were to eat sparingly of gluten bread.²

As for soups, I would advise you to keep clear of those made with gluten grains, as well as all rich broths. Here Boussingault has given us interesting facts showing that there is a large percentage of feculent matter in these soups.

As for green vegetables, I think that they may safely form a part of the dietary of diabetic patients, and in this opinion I am supported by Bouchardat. Water-cresses may be freely indulged at meals, also dandelion greens, artichokes, spinach, celery, cooked salads, etc. I know that green vegetables include notable quantities of saccharine matters, but they contain also potash, which is good for diabetic patients.

As for fruits, you should be very chary in their employ. The analyses of Mayet are very conclusive in this regard. Nevertheless melons, raspberries, gooseberries, and even oranges may be permitted under certain restrictions.³

As for alcoholic beverages, there are certain which are permitted, and others which are forbidden. Champagne, malt beer, and ale are interdicted; the same may be said of the effervescent, non-intoxicating drinks, lemonade, ginger beer, etc. Bordeaux and Bourgoingne wines may, however, be allowed, as well as coffee and tea without sugar.

But you must avoid the deleterious effects of alcohol on the economy. A great many diabetics, to satisfy their intense thirst, drink great quantities of wine and

figs, bananas, pears, apples, and melons. All jellies and preserves, all sweetened aliments or drinks, honey, milk, cider, beer, frothy or sweet wines, effervescent waters, lemonade, and other acidulous drinks, etc.

Wheaten flour, and flour from all other cereals, should be excluded from sauces, and gluten flour used instead; also the yolks of eggs, butter, and cream.

It was in 1841 that Bouchardat first called attention to gluten bread. To obtain gluten the flour is first washed for some time (twenty minutes to several hours, according to the purity of the flour) in a metallic sieve, No. 120. A paste is first made, and it is this paste which is submitted to constant irrigation. The fresh gluten thus obtained equals about one fourth the weight of the meal employed. The gluten should be used fresh and made into bread or cakes for glycosuric patients.

Boussingault and Mayet on analyzing these gluten cakes and this flour have shown that they still contain a considerable proportion of starch; from sixteen to forty-four per cent.

¹ Bran bread has been highly extolled by Camplin in the treatment of diabetes. (Camplin, on Diabetes and its Treatment. London, 1864.) This is his recipe for bran cakes: Take three ounces of wheat bran, three fresh eggs, two ounces of butter, one pint of milk, stir well together, and flavor with nutmeg or ginger. Place this dough in hot cast-iron baking pans, well buttered, and put in the oven for half an hour. Eat these biscuits instead of ordinary bread.

Pavy's bread of sweet almonds is made by first treating the almonds, reduced to fine powder, with boiling water slightly acidulated with tartaric acid, which deprives them of six per cent. of sugar. Of the paste thus obtained biscuits are made.

Dahmen's bread is made as follows: Soak wheaten groats half an hour in cold water; knead the dough thus formed in a stream of cold water, desiccate the glutinous residue, and triturate in a mortar. Take 165 grammes of this powder, mix thoroughly with one third quart of sour milk, add 125 grammes of melted butter, ten eggs, a little salt, and some carbonate of ammonia. When this mixture has acquired a pasty consistency place in French roll pans, well buttered, and consign to a hot oven till well cooked. (Berlin. klin. Woch., September, 1880.)

² Amount of sugar in 100 grammes:—

Turnips	7.00.	Lentils cooked and drained	22.50.
Baked potatoes	8.30.	Rice cake	25.00.
Rice (cooked in water)	8.00.	Fresh gluten bread	27.70.
Peas (boiled)	12.00.	Lancry's gluten bread	31.15.
Pea soup	15.60.	Bread of the Vichy Com-	
Beans	16.00.	pany	31.00.
Carrots	16.60.	Ordinary bread	60.00.
Chestnuts	20.00.	Ordinary flour	71.00.
		Ordinary starch	83.00.

³ The analysis of Boussingault shows that cabbages, chicory, turnips, carrots, beets, potatoes, and spinach contain from two to four per cent. of potassa.

The analysis of Mayet shows that the following fruits contain the percentages of glucose herewith given:—

	In 100 grammes.		In 100 grammes.
Gooseberries	1.50 to 8.00.	Peaches	10.50.
Melons	7.50.	Figs	15 00.
Raspberries	1 to 8.00.	Prunes	16.00.
Oranges	10.00.	Dried prunes	42.00.
Cherries	10.25.	Dried figs	71.00.
Dried raisins	76.00.		

(Mayet, Note on Sweet Fruits from the Point of View of their Introduction into the Dietary of Diabetics, Union Med., 1873.)

other alcoholic preparations. Such excesses are very detrimental. Bouchardat would limit diabetic patients to one quart of wine a day.

This subject of drinks is a very important one, for it is a pressing indication to diminish the excessive thirst which plagues diabetic patients, and many of them will keep demanding of you what they shall drink. I am much in the habit of ordering Vichy water, or water holding in solution from five to ten grammes of Seidlitz salts, or even mild bitter infusions, as of cinchona, hops, quassia, camomile, but it is well to urge the patient not to yield to his thirst, but to combat it as far as possible.

Apropos of these beverages I ought to mention the employment of glycerine¹ in the treatment of diabetes. This triatomic alcohol gives good results in this disease, if we may trust to the experience of Schultzen, Harnach, and Holtz. In fact in the case of those patients who cannot tolerate the entire suppression of sugar in their drinks glycerine may sufficiently replace it, but it is necessary to protest against the large doses which have been recommended, for we have demonstrated (Audigé and myself) that glycerine may become toxic.²

Therefore, to recapitulate, these are the rules on which you should found the alimentation of diabetic patients: total abstinence from sugar and from sweetened food; diminution as complete as possible of amylaceous substances; animal food and fresh herbs, care being taken to select such vegetables and such feculent articles as have the least quantity of saccharine matters; almost entire abstinence from bread, Bordeaux wine, bitter drinks; no distilled liquors nor sweetened beverages.

The diabetic invalid, habituated to good cheer, ordinarily a high liver, will ask of you not only general indications but also particular details respecting the manner of varying his daily bill of fare. You will be able to satisfy this demand by consulting the "menus" of Bouchardat, that I place in part before you,³ and which should guide you in the choice of your culinary preparations, but do not forget that the rules which I have just prescribed, and which have also been

adopted by Seegen, are not immutable, and that you will be compelled in many circumstances to make compromises in the rigorous application of this dietetic regimen, for if it is dangerous for a diabetic to eat feculent and saccharine substances, it is more so to see him reject all kinds of food with disgust. In fact I cannot do better than to remind you of what has taken place in our female wards, where we had lately occupying No. 1 a lady patient suffering from the grave form of diabetes, and whom we have sent to Vichy. This woman, much emaciated, was losing more than 400 grammes of sugar a day. We desired to submit her to an exclusive regimen of meat and herbs, but she could not make a meal without bread, and gluten bread, as well as other kinds of hard bread, were intolerable to her. Therefore this privation of bread had resulted in loss of appetite, and if under the influence of abstinence we indeed did see the sugar diminish, we observed at the same time a circumstance of great gravity, namely, enfeeblement of the forces. On this account we yielded to the desire of the patient, and allowed her a small quantity of bread with each meal. What we did you will often have to do, but take care always to test the results of your dietetic prescriptions by daily analyzing the urine, and in this analysis the saccharimetric process of Dubomme will render you great service in enabling you expeditiously to examine each day the effects of alimentation. The hygiene of the diabetic does not consist exclusively in attention to diet, it is necessary also by physical exercises, varied and multiple, to energize the combustion of hydro-carbonaceous matters. Here, moreover, it is Bouchardat who has furnished the best indications to follow in the forced exercise of diabetic patients, and you will find described with a great deal of humor the main features of these forced exercises in the spirited work of Jules Cyr. All that can augment the forces of the economy ought to be employed in these cases, and it would be well to vary these exercises according to the needs of the patients. Gymnastics, fencing, forced marches, work in the garden, manual exercise, carpentry, all have their place and their use. You may even add to these means inhalations of oxygen, baths of compressed air, inhalations of compressed air, in a word, all measures which may increase the organic combustions in rendering more active the respiratory functions. In fine Bouchardat has also insisted on the necessity of special attention to the functions of the skin. You know, in fact, that in grave cases of diabetes the skin becomes dry and rugose, hence warm baths followed by massage are useful in such cases, and may be taken two or three times a week. With this hygienic treatment you can in mild cases cause the glycosuria absolutely to disappear. In diabetes of medium intensity you will considerably lower the amount of sugar, but you will have to conjoin certain medicines, and it is these medicaments which I am now going to consider. I propose to pass rapidly over the pharmaceutical agents whose medicinal action in diabetes is not satisfactorily demonstrated, to dwell more particularly on three of them which possess marked curative virtues. I refer to the alkalies, arsenic, and bromide of potassium.

Certain antiseptic remedies have been much vaunted these late years, such as salicylic acid and carbolic acid. Ebstein and Muller, Ryba and Plumert, Fischer and Peters, have recommended this method of treatment. According to Fürbringer, these anti-fermentescible substances are much superior to the other pharmaceutical

¹ Schultzen, of Dorpat, has counseled the use of glycerine in diabetes, which he considers a powerful adjuvant to the ordinary alimentary regimen. The same may be said of Garnier; both give twenty to twenty-five grammes (or somewhat less than an ounce) daily. Harnach recommends still larger doses, from 180 to 360 grammes a day (or from six to twelve ounces), and affirms that these quantities have no injurious effect, have no influence on the amount of sugar eliminated, and rather favor the amelioration of the patient. Holtz believes that glycerine has not merely a neutral effect as far as the glycosuria is concerned, but that it decidedly lessens sugar excretion. (Garnier, on Glycerine in the Treatment of Glycosuria, Comp. Rend. de l'Acad. des Sc., 10 Mai, 1875. Harnach, on the Treatment of Diabetes by Glycerine, Deutsch. Arch. f. klin. Med., vol. xv., p. 449. Holtz, Ueber Diabetes, Petersburger. Med. Woch., No. 3, 1880.)

² Dujardin-Beaumetz and Audigé, on the Properties of Glycerine. (Bull. gen. de Ther., t. xci., pp. 51 and 135.) Also, Experimental Researches on the Toxic Power of the Alcohols. Paris, 1879.

³ [The "menus" of Bouchardat are omitted, as being more applicable to the gourmands of France than of this country. In brief, soups with cabbages and leeks, without bread or flour, are permitted, also rich broths with gluten crackers. Meats of almost all kinds are allowed, with *hors d'œuvre*, as before given (*vide supra*); eggs, shell fish, salads, and *entremets* of gluten cakes, waffles of gluten flour or pure bran, jelly with rum, *kirsch*, or coffee without sugar, omelets with rum (not sweetened), and vanilla. He also specifies as allowable, among the *entremets*, artichokes, cabbage, with sauce, oil, gravy containing gluten flour, or Parmesan cheese. Chicory, lettuce, and other herbaceous vegetables; asparagus, spinach, mushrooms, etc. If tea and coffee (which should never be sweetened) have no influence favoring the glycosuria they may be indulged in. Alcoholic liquors should be used with great moderation. Of wines (a quart a day for a man, a pint for a woman), choose the old red wines or the old white wines (Madeira, Chablis, Pouilly, Sauterne, Rhine, etc.). TRANS.]

agents. The trials which I have made with these medicines on divers of my patients, both in hospital and private practice, have not given me such good results. I have not observed notable diminutions in the sugars, and I have seen, like Kamen, gastric troubles, and I believe that there is risk in administering large doses of these phenols to some diabetic patients by reason of the bad state of their kidneys. To these medicaments we must add permanganate of potash, proposed some time ago by Sampson, of London, and which Masoin, of Louvain, has recently brought into vogue. This permanganate of potash may have a good effect on diabetes of hepatic origin. Cantani has asserted the favorable action of lactic acid in the treatment of diabetes. He thinks that this acid favors the digestion of animal food and the organic combustions; it is even, according to him, the unique medicine to give to the diabetic. As I have never advised the exclusive diet of the Italian physician, I have not used his pharmaceutical treatment, I cannot, then, give you any information on the employment of lactic acid. Ogles pretends that this medicament diminishes the quantity of sugar, but at the same time lessens the weight of the patient. Struck with the action of certain narcotics, such as opium, belladonna, valerian, on the quantity of urine voided each day, it has occurred to physicians to reduce the polyuria of the diabetic by the use of opium, and it is on this principle that Willis, Rollo, and Tomasini have advised this medication. Diabetic patients, in fact, bear opiates well even in very large doses, and you may note in some of them a diminution of urine and in the quantity of sugar, but this result is obtained at the sacrifice of the digestive functions and of the appetite. This is an evil which attends the use of a great many pharmaceutical preparations, and is to be avoided. To lessen the sugar in the urine by diminishing the appetite and troubling the digestive functions is to render a very poor service to the diabetic. Valerian is more applicable to *diabetes insipidus* or polyuria than to *saccharine diabetes*. Trousdale has shown that under the influence of this medicament there is a diminution in the quantity of urine, on condition always of giving large doses, and he was in the habit of administering as much as an ounce a day of the extract. Ergot of rye acts also against polyuria rather than against glycosuria, and Huchard has recently shown the good effects which may be obtained from the spurred rye in *diabetes insipidus*. Iodine and the iodides have also been employed in the treatment of glycosuria. Ricord, Berenger-Feraud, Rayer, and Seegen principally have exhibited the tincture of iodine in the dose of from twenty to thirty drops a day, and have seen the sugar disappear from the urine, but it is an irritant medicament and fatiguing to the stomach. I pass rapidly over the chalybeates, phosphorus, cantharides, pilocarpine, the juice of *cana-agria*, to arrive, at last, to the consideration of the alkalies, arsenic, and bromide of potassium.

The alkalies are the most precious pharmaceutical agents in the treatment of diabetes, although we have no very clear explanation of their therapeutic action. Miahle having pretended that glycæmia depends on want of alkalinity of the blood was one of the first to recognize the utility of alkaline medication, but, as Becquerel and Lapezzuoli have shown, this is a mistake, for the blood of diabetic patients presents no modification in its alkaline reaction.

It is probable that in diabetes the alkalies have a complex action; they regulate the digestive functions, and energize the functions of nutrition (as shown by the researches of Hyades and Martin Damourette), in fine, it is possible that they have, as Coignard thinks, a direct action on the glycogenic functions of the liver.

Many alkaline preparations have been prescribed; some, as Rollo, Willis, Fothergill, and Wat, have counseled lime-water; others, as Dur, Neumann, Barlow, Adamkiewicz, prefer the ammoniacal salts; Bouchardat and Pavy have especially advised the carbonate of ammonia.

Potassa has also been exhibited, and Bouchardat, who cannot be too much cited when diabetes is under consideration, has proposed to substitute for the common salt in the ordinary dietary of the diabetic the potassic tartrate of soda, known as Rochelle salt. This preparation he considers superior to the citrates of soda and potassa, which he was formerly in the habit of prescribing. He even advises the use of the Seidlitz salt in the preparation of diabetic bread. But the alkaline salt the most employed in the treatment of diabetes is the bicarbonate of soda, and here we must give the preference to the natural alkaline waters over the artificial waters, which fatigue the stomach, and cannot be borne for any great length of time. You will then order your diabetic patients to drink with their meals waters with but a moderate degree of alkalinity, say two or three grammes per litre, and there is nothing better than the Vals or Vichy waters.

Arsenic has these late years been much extolled in the treatment of glycosuria. It has been supposed that arsenic, in modifying the constitution of the liver, modifies also the glycogenic functions, and the recent experiments of my colleague, Quinquaud, have shown that this medicament always diminishes in animals glycæmia, glycosuria, and glycogenesis. This is a fact of great importance, and shows us the advantages which may be derived from arsenical medication in diabetes. Fowler's solution is the best form to choose; of this you need not fear to give large doses, even twelve to fifteen and twenty drops, according to the tolerance of the digestive tube.

Arsenic is not the only metal or metalloid used in diabetes, iodine has been prescribed, and even copper and mercury, the first by Franck and Berndt, the second by Brera and Scott. Burq has even thought that his process of metallotherapy and metalloscopy has a field of usefulness in these cases.

The attention of the medical world has of late been called to the curative action of bromide of potassium in diabetes by a very interesting communication by Dr. Félizet to the Académie de Médecine. Félizet has shown that in certain cases in following the dietetic régime of Bouchardat and the alkaline medication by bromide of potassium, one may free the urine entirely of the sugar which thus far has persisted in making its presence manifest.

This is a kind of treatment which was counseled by Beghie in 1866, but which being tried anew by other physicians had not given very favorable results. In the trials which I made in my service, and in the report which I presented to the Academy of Medicine on this subject, while recognizing the fact that bromide of potassium in the dose of one to two grammes a day may cause glycosuria to disappear, just as Félizet had announced, I showed that the use of this medicine was not without inconveniences. It depresses considerably

the forces, and this depression is sometimes so great that the patient is not able to leave his bed. I think, then, that it is necessary to be very prudent in the administration of medicaments of this character, and reserve them for cases of diabetes of nervous origin, and for patients sufficiently vigorous to support such treatment.

The thermal treatment of diabetes is of preponderating importance, and the results which may be derived from it are based on the physiological effects of alkalies and arsenical salts in glycosuria. It is, then, to the alkaline and arsenical spas that you should send your patients, and you may utilize the alkaline waters of Vichy and of Carlsbad, or those of Royat and Bourboule if you desire especially for your patients the constitutional effects of arsenic.

I shall have finished this long enumeration of the means of treatment of diabetes when I shall have said a few words about the local treatment of diabetes by electricity, hydrotherapy, setons, and cauteries.

It was Semmola who, in 1861, first recommended the employment of constant currents upon the pneumogastric in the treatment of diabetes. Leidel and Prof. Leon Le Fort have obtained good results from galvanism.

Flcury has counseled hydrotherapy. I believe that it is necessary to be very careful in the use of this hygienic remedy, and not to employ it except when your diabetic patients are robust, and capable of vigorous reaction.

The same prudence should be exercised in the use of setons and cauteries. Butura and more recently Boutigny have noted cases of diabetes where complete disappearance of sugar from the urine followed the application of cauteries and setons in the region of the neck. But you should remember the danger of wounds (which do not readily heal) in the case of diabetic patients, and be extremely cautious about attempting treatment of this kind.

Such are the therapeutic rules applicable to the treatment of diabetes. Here the dietetic regimen is far the most important, all other modes of treatment being accessory means whose real value is often more or less debatable. But whatever this value may be, the combination of these means none the less constitutes an efficacious system of therapeutics, and without daring to affirm, as some have done, that diabetes is to-day a disease easily and certainly curable, I believe that in a very great number of cases we can have a useful and a real influence on the disease, and this is why I have devoted so much time to the consideration of these details.¹

Original Articles.

A NEGLECTED FIELD OF MEDICAL SUPERVISION.²

BY C. B. SHUTE, M. D., MALDEN.

THOUGH with some hesitation as to whether the time of presenting the subject is an opportune one, yet on account of its importance I have ventured to call your attention to a field of medical supervision, hitherto for the most part neglected, but in which the medical profession may confidently hope to exert a most salutary

¹ [Dukomme's *Rapid Analysis of Diabetic Urine*. Codman & Shurtleff, of this city, inform us that they are prepared to furnish the graduated dropping tubes of Limousin referred to in the portion of this lecture given in last week's JOURNAL. See pp. 459, 460.]

² Read before the Middlesex South District Medical Society, October 10, 1883.

influence, and to effect results beneficial as well as brilliant. There is a class of sufferers who are numbered by thousands, in this as well as in other commonwealths, and who are constantly forced upon our notice in the daily rounds of our practice, and yet we, as physicians, although aware of their need, are doing almost absolutely nothing for their relief. I refer to the class of chronic inebriates.

It is true that we are occasionally called to treat complications arising from the abuse of alcohol. To this we can often trace many of our cases of Bright's disease, cirrhosis of liver, phthisis, many affections of the cerebrum, and nervous system in general. It is mostly in such forms of disease that these unfortunates close their mortal career, and we are called to them during the last days of their existence. But it is also true that during the long period of their downward course we have little to do with them as a class. Perhaps this arises in a great measure from the fact that they do not regard themselves as needing medical assistance, and therefore do not call for our services. Even if we were to offer any advice in such cases, it would generally be rejected, so that the fact remains, as before stated, that chronic inebriates are for the most part untreated.

To avoid misunderstanding, it is necessary to indicate more precisely what persons are intended to be included in this class. I have no reference to that large number of moderate drinkers who, while taking their daily potion of spirit, never suffer themselves to indulge in any excess, nor yet to that smaller group of periodical drinkers, persons who are perhaps totally abstinent from alcoholic liquors for a certain length of time, but now and then give themselves up voluntarily to a complete debauch, which may or may not terminate in an attack of delirium tremens, but is followed by another period of voluntary abstinence. By the expression "chronic inebriates" is meant that class of persons who have lost all self-control in their passion for drink, who have no ambition to work or engage in any employment, except perhaps so far as it may furnish them the means for the gratification of their appetite; in short, whose whole aim in life seems to be indulgence in some form of alcohol. These worse than drones, who infest every community, are more numerous than would at first appear. Look around you in your own town or village and you will be surprised at the number you may find. It is certainly not an over-estimation to rate this class as numbering five persons in every one thousand. This will give for this Commonwealth the large number of about nine thousand persons. If to this number we add the families who are made sufferers by the failure of these wretched persons to provide for their proper support, we have a grand total of about forty thousand people who are the victims of this great evil in this State alone.

It may be claimed at the outset that this is not a question for the medical profession, that it belongs to the philanthropist, to the preachers and their churches, to the temperance worker; in short, that it is a question of moral reform. I have no desire to trespass upon the sphere of work of the above-mentioned persons, nor indeed to discuss in the least the question of temperance. If the class of unfortunates now spoken of could be reached by any such moral agencies, I should feel that we might safely leave them to such influences. But what moral influence can avail with this class of people? What appeal from such a source

would affect the course of any of these confirmed drinkers, who, like the Rip Van Winkle of Jefferson, are always ready to exclaim that "this glass don't count?" The fact is, that in losing their self-control, that is, their power of shaping their own course by an effort of their own will, they have also lost all susceptibility for improvement from any moral influence. The work of these reformers may lie with the other two classes mentioned, but not with the class under consideration. The latter may be regarded as hopeless so far as moral reform is concerned.

Again, it may be objected that these persons, instead of being subjects for medical treatment, are victims of a vicious habit, and should therefore be considered as criminals, and be subjected to a suitable legal punishment. This brings me to the pith of the subject. Are they criminals, or are they subjects of disease? If they are criminals, then we, as physicians, have nothing to do with them. If the latter alternative is the case, then they fall under our jurisdiction.

There are few who will hesitate to acknowledge that mankind in all ages and in all conditions of life has an instinctive, inborn craving for some form of stimulation. This, like other propensities and passions which go to make up the human character, is in most persons entirely under the control of the will. Most men may will or not to indulge in alcoholic drinks as they please. Even most of those whom I have grouped in the second class, namely, those who give themselves up to occasional or periodical debauches, really yield to these excesses of their own accord, having the power all the while of restraining themselves, a power which they do not care to exercise. They wish to have a debauch, and they have it.

Unfortunately all persons are not so constituted that they can exercise entire freedom of their will in such matters. Subject to adverse hereditary influences, and reared under circumstances which only tend to strengthen and make more prominent certain inherent tendencies, they are powerless to resist their certain destiny. They are swept onward towards the maelstrom which is certain to engulf them. They are veritable monomaniacs in the attempt to secure the accomplishment of their desires. No ordinary motives of self-interest or regard for health or prosperity or care of friends have any effect upon them. They are bent on indulging their own appetites, regardless of its consequences upon themselves or friends. Surely this is a frenzy which borders closely upon, if it is not in reality, a form of insanity. We cannot regard these ill-fated ones as criminals, for they are not responsible for the circumstances under which they were born and reared, and which brought them to this pitiable condition. They have diseased brains, and we should care for them as we do for others who are bereft of reason. Dipomania is as truly insanity as the homicidal or suicidal mania or kleptomania. Apply the tests of insanity to the cases under consideration, and they fulfill all the conditions. They have not been so considered in the past, and they have consequently been neglected. We cannot escape the conviction, if we would, that this class of unfortunates comes strictly within the jurisdiction of the medical profession.

What say the medical authorities upon this important point?

Professor Boehm speaks of the want of character, or want of individuality, of chronic inebriates. In such cases, he says, we do not know if the craving for

drink, the alcohol mania, be the original cause of the malady, or whether we must regard the craving as itself one of the symptoms, unless we have watched the development of the disease from its very beginning. Continual struggles with temptation and continual yieldings to it reduce the man, who was, perhaps, at first a well-meaning person, to a state of irreconcilable conflict and dissension with himself, with duty, and with all the world around him. His power of resistance grows gradually weaker and weaker, whilst at the same time, step by step, his intellectual and physical powers grow more and more feeble. In this category one often finds men of position and eminence—high-class men in every sense. And just in proportion to the original development of what we may call the higher ethics is the psychical conflict increased, and is the completeness of the moral ruin. Sots of the lower orders do not fall so low, because they have never climbed so high. Comparatively few are reclaimed in the long run. Very many, indeed, put an end to their own lives, but the great majority perish by intercurrent diseases, or are attacked by general paralysis.

Anstie mentions as one of the most influential causes of alcoholism a peculiar inherited constitution of the nervous system. He says that he has been greatly struck with the number of drinkers who have informed him that their relatives, either on the paternal or maternal side, have also been given to drink. And a still larger number are found, on inquiry, to come of families in which some nervous disorders (especially insanity, epilepsy, and neuralgia) have been markedly prevalent. His own experience has led him to a firm conviction that particular causes of nervous degeneration affecting individuals do very frequently lead to the transmission to the offspring of those persons of an enfeebled nervous organization which renders them peculiarly liable to the severer neuroses, and which also makes them facile victims of the temptation to seek oblivion for their mental and bodily pains in narcotic indulgence. He believes that things often work in a vicious circle to this end; and that the nervous enfeeblement produced in an ancestor by great excesses in drink is reproduced in his various descendants with the effect of begetting insanity in one, epilepsy in another, neuralgia in a third, alcoholic excesses in a fourth, and so on. Among the higher classes careful inquiry elicits facts of this kind with surprising frequency. So strong is the impression left on his mind by what he has observed in this direction, that he is inclined to believe that the great majority of the most inveterate and hopeless cases of alcoholic excess, among the higher classes, are produced by two factors, of which the least important is the circumstance of external momentary temptation in which the patient has been placed, while the more momentous and weighty cause lies in an inherited nervous weakness which renders all kinds of bodily and mental trouble specially hard to bear. It need hardly be remarked that, in view of this case, the fatal rapidity with which habits of intemperance exaggerate themselves is only what might be expected, seeing that the nutrition of the nervous centre would be still further impaired by each successive indulgence in poisonous doses of alcohol, and the power of moral resistance to feelings of depression and misery would be proportionately weakened.

Anstie speaks of oinomania as a variety of constitutional insanity rather than of alcoholic disease. The

sufferers are usually descended from families in which insanity (and often insanity of the same type) is hereditary. Patients of this class very commonly display their tendencies early in life; sometimes, indeed, on the very first occasion on which the opportunity for the free use of strong drink presents itself.

Brühl-Kramer says that alcoholism in the father is worse as regards offspring than alcoholism in the mother.

The hopelessness of the case lies in the taint of insanity which almost always is at the foundation of the complaint, and which makes it almost impossible that the patient can effect a thorough reformation of his habits. However virtuous his intentions may be, and however strongly he may be urged by every consideration of prudence, or affection for those whose interests may depend upon his conduct, it appears as if he were impelled by a really irresistible force to yield himself, at certain intervals, to the temptation of drink. When the outbreaks become, as they usually do in the end, greatly more numerous than at first, there is reason to apprehend the speedy superposition of confirmed insanity. In this condition of things "pledges" of reform are of no avail. As Anstie says, "Pledges" have a tendency to lessen the force of such notions of personal responsibility as he may retain; he is apt to rest his confidence on the oath or formal resolution which he has taken, instead of teaching himself the virtue of self-restraint.

Morel says that not only is the vice of alcoholic abuse hereditarily transmissible, but it also frequently leads to insanity in the offspring of the drunkard. He gives a remarkable example of this. The great grandfather of the family was a dipsomaniac, and so complete was the transmission of the disease, that the race became totally extinct, under the well-marked phenomena of alcoholic poisoning and degeneracy. The effects entailed were: in the first generation, alcoholic excesses, immorality, depravity, brutish disposition; in the second generation, hereditary drunkenness, attack of mania, general paralysis; in the third generation, sobriety prevailed, but hypochondriasis, lypomania, persistent ideas of persecution, homicidal tendencies, were expressed; in the fourth generation, intelligence was but feeble; mania became developed at sixteen years of age, stupidity running on to idiocy, and to a condition involving extinction of the race.

The late Dr. S. G. Howe, in a report on idiocy made to the Legislature of Massachusetts, came to the conclusion that "directly or indirectly alcohol is productive of a great proportion of the idiocy which now burdens the Commonwealth of Massachusetts."

In an annual report of the hospital at Columbus, Ohio, Dr. Hills says of one of his patients that his father, in the first part of his married life, was strictly temperate, and had four children, all yet remaining healthy and sound. From reverses of fortune he became discouraged and intemperate for some years, having in this period four children, two of whom we had now received into the asylum, a third was idiotic, and the fourth epileptic. He then reformed in habits, had three more children, all now grown to maturity, and to this period remaining sound and healthy.

Another similar case follows: An intemperate parent had four children, two of whom became insane, one was an idiot, and the fourth died young in fits. Four children born previous to the period of intemperance and two after the parent's reformation are all sound and healthy.

Ray refers to that insatiable propensity to drink which impels the person to indulge in spite of the strongest possible inducements to refrain, as if the will were powerless and the moral sense somewhat blunted. It differs from the ordinary fondness for drink, in which, no doubt, it generally originates, in being beyond the control of any conceivable moral consideration, and connected, probably, with some pathological condition of the brain. It is manifested under two general forms. In one the person proceeds from one excess to another and a greater until a maniacal condition of the brain is produced, when he becomes unconscious of his acts, and often disposed to violence. In the other he retires to some secluded place, and there quietly and alone rapidly imbibes large quantities of liquor until the stomach refuses to receive any more. He then remains for a time in a stupid, listless state, which is succeeded by the natural condition, and this, after an interval more or less brief, by a repetition of the same scenes. In both cases the individual seems to have no more moral freedom than the true maniac has while committing his extravagances. He is entirely under the dominion of an organic impulse by which he is led automatically and sometimes unconsciously. In the early stages of the paroxysm he may appear to be aware of what he is about, and fancy that he is only indulging within reasonable limits. He feels quite secure, and every remonstrance is indignantly answered in a tone of injured innocence. Or he may admit to the fullest extent the enormity of his sin and his peril, while he deplores his utter inability to resist the appetite that rages within him.

Macnish, in his *Anatomy of Drunkenness*, relates the case of one who thus replied to the remonstrances of his friend: "Your remarks are just; they are, indeed, too true; but I can no longer resist temptation. If a bottle of brandy stood at one hand, and the pit of hell yawned at the other, and I were convinced that I would be pushed in as sure as I took one glass, I could not refrain. You are very kind. I ought to be very grateful for so many kind, good friends, but you may spare yourselves the trouble of trying to reform me; the thing is out of the question." And thus it is that advice, admonition, and reproach are all equally lost upon this class of persons, and the end is the same in nearly all—they lose all rational control over their conduct, abandon their employment, desert or abuse their families, and though they commit no act of violence they at least destroy the peace and threaten the safety of those around them.

Bucknill and Tuke define dipsomania as an uncontrollable and intermittent impulse to take alcoholic stimulants or any other agent which causes intoxication. They say that the prominent feature of the disease is its irresistibility; the thirst for drink is the tyrant which overbears all the higher emotions, and blindly leads the oinomaniac to a course against which his reason and his conscience alike rebel.

(To be continued.)

— Attar of rose, one minim to the drachm of iodoform, will, on the principle of the survival of the fittest, it is said, get the better of the odor of the latter drug, and the patient, instead of a social Pariah, may become a garden of delights unto himself and all his neighbors.

A CASE OF MALIGNANT DISEASE OF THE UTERUS.¹

BY W. E. BOARDMAN, M. D.

IN August, 1878, Mrs. A. was referred to me by a physician of this city. She was a lady, fifty-two years of age, who had always enjoyed excellent health, of good physique, but inclined to corpulency, with no hereditary tendencies to disease so far as could be ascertained, the mother of four children, all living at the time, at whose birth nothing unusual to normal labors appears to have occurred, and until the commencement of the present illness she had not had her attention directed in any way to the pelvic organs except by the proper performance of ordinary functions. A lady of refinement by birth and education, and highly cultured, she was always of a cheerful disposition, methodical and abstemious in her manner of life, though possessed of abundant means. The menopause had been completed several years before, at the age of forty-five, without any noticeable disturbance of the system. Since that period she had continued in her usual good condition both mentally and physically. In the previous spring, in February or March, I think, five or six months before I first saw her, she was surprised at what appeared to be a return of menstruation, though the flow was more profuse than it used to be. There was no pain attending this, and it might have been forgotten had it not been followed by a slight leucorrhœal discharge, thin, watery, clear, and inodorous, becoming later of a dirty color, emitting a disagreeable smell, and increasing in quantity. It was this discharge which led her to consult a physician, a lady of large experience. Remaining under her professional care for a time, and without any relief in the way of correcting the discharge, she decided to consult me, by the advice of her family physician. (I afterwards learned that her husband had been given an unfavorable prognosis by this her first medical attendant.)

At the first visit I found the patient in excellent condition generally, in complexion, physique, nervous and muscular energy. The functions were well performed in all respects. Nothing troubled her except the leucorrhœa. There had been no recurrence of the hæmorrhage per vaginam. The discharge at this time was inodorous, clear, albuminoid in appearance, but sufficiently abundant to require the constant use of napkins. There was no pain; no tenderness under pressure over the lower abdominal region. The vagina presented nothing abnormal. The uterus was not enlarged, though atrophy had not ensued. The cervix was perfectly healthy in appearance; the os was quite patulous, though there was no eversion of the lips of the cervix. The position of the organ was normal; it was freely movable in any direction and without pain or undue sensitiveness. Its depth, as measured by the sound, was two and one half inches. The introduction of this instrument did not occasion bleeding. The patulous condition of both external and internal os enabled me to introduce readily Thomas's soft wire curette, with which I succeeded in removing only, perhaps, two or three particles which looked like granulation tissue, while otherwise the interior of the uterus appeared to be perfectly smooth and healthy. Knowing, then, that she had been under local treatment for some time, I concluded that she was either about cured

or that, perhaps, some application had been made within the uterus which had given rise to these granulations. At all events I stated at the time that so far as I could then ascertain she would probably soon be quite well again.

At a subsequent visit, one week later, the discharge was pronounced less in quantity, and nothing new in the case was detected. The following week she was seen again, and reported improvement. The curette was introduced again, and brought away, with some hæmorrhage, readily controlled with iodine, an increased amount of supposed granulation tissue, together with several small sago-like particles, which the patient stated resembled some she had previously observed on her napkin, and which she very aptly called "barnacles." Moreover, when pressed, some of these particles emitted a notably offensive smell. Dr. E. G. Cutler, of this city, kindly examined these, and sent me the following communication in regard to them:—

"September 18, 1878.

"I have examined all those pieces carefully, and do not find anything characteristic of either epithelioma, sarcoma, or carcinoma. There is a papillary increase of all the tissues, and it may be malignant. I had the examination of another such two years ago. I mean locally malignant. It has returned in spite of repeated destruction, and you want nothing more than this, provided you are sure you destroyed it before, to make it a growth to be afraid of. I should on the whole regard it unfavorably. There did not seem to be anything like cell infiltration in any of the specimens, which is characteristic of malignancy."

Acting upon this opinion I was necessarily obliged to modify somewhat my previous favorable prognosis. A week later the curette indicated a slightly roughened surface, as large as a common bean in its outline, on the upper and anterior portion in the right side of the cavity, and from this limited area alone these "barnacles" could be scraped. The remaining portions of the uterus and cervix appeared to be perfectly healthy.

One month later, October 25th, my notes of the case state that the diseased area had gradually diminished in extent, but the discharge continued without perceptible change in quantity or quality.

In the following month my notes convey the information that the fundus appeared to be free from disease, but that upon the interior of the body, just within the internal os, a similar roughened locality had made its appearance, involving an extent of surface equal to half the circumference of the cervix at that level. In the middle of the next month the same disease was detected again at the fundus, in the same locality as before, while it had not disappeared from within the internal os. From this time my attention was directed to these two diseased localities. The curette, both dull and sharp, liquid applications of various kinds, used alone and after the employment of the curette, appeared to have no effect in eradicating the disease, though its extent did not seem to increase so long as treatment was applied at tolerably frequent intervals. In the mean time the discharge continued to increase somewhat in amount, and became more, offensive so that frequent ablutions were required in order to avoid the detection of the odor by others.

In the summer of 1879 she went as usual to her sea-shore home, and for one month, from July 9th to August 9th, I did not visit her, partly in order to as-

¹ Read before the Boston Society for Medical Improvement, November 12, 1883.

certain if she would not do as well without any treatment. At my visit, after this interval, I found the area of disease, in both localities, was increased. She reported that, on two occasions, she had expelled, with slight pain, a cylindrical mass, as large as the little finger, and one to two inches in length, gray in color, quite dense in appearance, easily broken up, and emitting a most foul stench. Her strength, too, had begun to deteriorate, notwithstanding the constant use of various tonics, and her face exhibited a sallowness peculiar to grave disease. A considerable amount of diseased tissue was removed at this visit, by means of the curette, and fuming nitric acid was applied. Before the arrival of the time for the next visit agreed upon she had an ill turn with chill, temperature 104.5° F., rapid respiration, flushed face, vomiting, and delirium.

Subsequent to this attack her strength returned slowly and imperfectly. While she suffered none from local pain or tenderness, she did not feel that she could submit to any local examination, and I did not visit her again until her return from the sea-shore, on October 25th. Examination then showed the uterus to be larger than it was a year before, the sound measuring a depth of a little over three inches, and its bulk, too, was greater as determined by manual manipulation. The cervix was still free from disease, except that the area of the diseased portion, which formerly stopped abruptly at the internal os, now extended a few lines within the supra-vaginal portion. Within the fundus, at its upper anterior portion, on the right side, the disease had extended so as to include an area measuring one half an inch by one inch. The uterus was still freely movable and without pain. The curette brought away granulations, sago-like particles, and a *grayish, stinking mass*, similar in appearance to the cylinder-shaped masses which have been described. A portion of this material was examined by Dr. Cutler, whose report was as follows:—

"A careful examination of the specimen shows that it is an animal membrane in a high degree of fatty degeneration. The membrane is tough, cuts like tendon or fascia, and is distinctly fibrous in its structure. There are several places much darker than the chief mass of the tissue. Degeneration has gone on so far that it is impossible to get a *perfect* idea of its histological structure, but enough remains to see that it is essentially fibrous. The dark portions were pigmented, and there were some hæmine crystals found in different places. It certainly is neither a mucous membrane nor a croupous one. The size and shape of the piece seem to indicate that it came from a somewhat large mass. I am inclined to regard it as a portion of a degenerating fibroid tumor,—considering the place it came from and its structure,—though why the patient does not suffer from the symptoms of auto-infection I do not see so plainly."

This communication served to puzzle me more than ever as to the nature of the disease. I was positive that there had been no clinical evidence of the presence of a fibroid tumor throughout the case, and requested Dr. Cutler to report upon three subsequent specimens, which he did as follows:—

"An examination of that mass shows less of a dense fibrous structure than that seen at first. It looks decidedly more like an extraordinarily tough croupous membrane than the first specimen I examined."

"November 17, 1879."

"The little fragment which you left me the other day is distinctly of the nature of a croupous membrane. That is, it is composed of coagulated fibrine, holding in its meshes some degenerated cells. I suppose the others were the same."

"December 1, 1879."

"Some of that matter looks like granulation tissue, and some like croupous membrane."

"December 13, 1879."

In the mean time the disease apparently had in some way acquired unusual activity, so that, in spite of the repeated application of the dull, and occasionally of a sharp, curette and the use of strong caustics, the mass increased both in the upper portion of the uterus and in the lower portion where a tumor projected within the cervix as large as a hazel-nut. The uterus became still more enlarged and less freely movable, and the cervix acquired a hard brawny feel. There was, too, some pain and tenderness upon movement. On January 2d, at about the time of my visit, a rather profuse hæmorrhage occurred, which, however, soon ceased with the employment of ergot. This was the only occurrence of flowing which the history of the case afforded, except at the very commencement of the affection.

Owing to the evident rapid development of the disease, the increasing discharge, the failing strength and general deterioration of the vital powers, I advised a radical operation under ether for the thorough removal of the disease, so far as this could be accomplished. This proposition received a ready assent, and on January 30, 1880, the operation was done by means of the finger nails and large, sharp curettes and scoops. A large quantity of diseased material was removed, apparently from the entire interior of the body and two thirds of the upper margin of the cervix, with considerable hæmorrhage, but unfortunately a specimen reserved for microscopic examination was thrown away by my servant. The patient rallied quite well from the immediate effects of the operation, but subsequently required daily uterine injections and frequent intra-uterine applications and curetting in order to keep under control the decomposition and attending stench, which would ensue in a brief space of time. In spite of this constant attention, a second formidable operation was done on April 15th, ten weeks after the former one. A specimen saved at this time gave the following report:—

"I have examined that specimen and find it more suggestive of a croupous membrane than anything else, though it is rather obscure."

"April 16, 1880."

From this time the patient maintained about the same condition for many weeks, suffering from no pain, complaining principally of weakness, but more of the annoyance which the daily routine of disinfection and cleansing necessitated. On two or three occasions she had pretty smart chills with rise of temperature evidently due to the plugging of the cervix with decomposed material and, therefore, considered to have been septicæmic in nature. The release of the plug, thus affording free escape to the discharges, prevented a repetition of this accident. There was no chronic septicæmia, for a constant watch of the temperature was kept, and this was found to average under 99° F.

In June a trial of Chian balsam was made, but, so

A CASE OF MALIGNANT DISEASE OF THE UTERUS.¹

BY W. E. BOARDMAN, M. D.

In August, 1878, Mrs. A. was referred to me by a physician of this city. She was a lady, fifty-two years of age, who had always enjoyed excellent health, of good physique, but inclined to corpulency, with no hereditary tendencies to disease so far as could be ascertained, the mother of four children, all living at the time, at whose birth nothing unusual to normal labors appears to have occurred, and until the commencement of the present illness she had not had her attention directed in any way to the pelvic organs except by the proper performance of ordinary functions. A lady of refinement by birth and education, and highly cultured, she was always of a cheerful disposition, methodical and abstemious in her manner of life, though possessed of abundant means. The menopause had been completed several years before, at the age of forty-five, without any noticeable disturbance of the system. Since that period she had continued in her usual good condition both mentally and physically. In the previous spring, in February or March, I think, five or six months before I first saw her, she was surprised at what appeared to be a return of menstruation, though the flow was more profuse than it used to be. There was no pain attending this, and it might have been forgotten had it not been followed by a slight leucorrhœal discharge, thin, watery, clear, and inodorous, becoming later of a dirty color, emitting a disagreeable smell, and increasing in quantity. It was this discharge which led her to consult a physician, a lady of large experience. Remaining under her professional care for a time, and without any relief in the way of correcting the discharge, she decided to consult me, by the advice of her family physician. (I afterwards learned that her husband had been given an unfavorable prognosis by this her first medical attendant.)

At the first visit I found the patient in excellent condition generally, in complexion, physique, nervous and muscular energy. The functions were well performed in all respects. Nothing troubled her except the leucorrhœa. There had been no recurrence of the hæmorrhage per vaginam. The discharge at this time was inodorous, clear, albuminoid in appearance, but sufficiently abundant to require the constant use of napkins. There was no pain; no tenderness under pressure over the lower abdominal region presented nothing abnormal. The uterus enlarged, though atrophy had not ensued was perfectly healthy in appearance; it patulous, though there was no eversion of the cervix. The position of the organ it was freely movable in any direction, without pain or undue sensitiveness. Its depth by the sound, was two and one half inches. The introduction of this instrument did not excite. The patulous condition of both externities enabled me to introduce readily the curette, with which I succeeded in removing, perhaps, two or three particles which looked like granulation tissue, while otherwise the interior appeared to be perfectly smooth and healthy. Then, that she had been under local treatment some time, I concluded that she was either

or that, perhaps, some application had been made within the uterus which had given rise to these granulations. At all events I stated at the time that so far as I could then ascertain she would probably soon be quite well again.

At a subsequent visit, one week later, the discharge was pronounced less in quantity, and nothing new in the case was detected. The following week she was seen again, and reported improvement. The curette was introduced again, and brought away, with some hæmorrhage, readily controlled with iodine, an increased amount of supposed granulation tissue, together with several small sago-like particles, which the patient stated resembled some she had previously observed on her napkin, and which she very aptly called "barnacles." Moreover, when pressed, some of these particles emitted a notably offensive smell. Dr. E. G. Cutler, of this city, kindly examined these, and sent me the following communication in regard to them:—

"September 18, 1878.

"I have examined all those pieces carefully, and do not find anything characteristic of either epithelioma, sarcoma, or carcinoma. There is a papillary increase of all the tissues, and it may be malignant. I had the examination of another such two years ago. I mean locally malignant. It has returned in spite of repeated destruction, and you want nothing more than this, provided you are sure you destroyed it before, to make it a growth to be afraid of. I should on the whole regard it unfavorably. There did not seem to be anything like cell infiltration in any of the specimens, which is characteristic of malignancy."

Acting upon this opinion I was necessarily obliged to modify somewhat my previous favorable prognosis. A week later the curette indicated a slightly roughened surface, as large as a common bean in its outline, on the upper and anterior portion in the right side of the cavity, and from this limited area alone these "barnacles" could be scraped. The remaining portions of the uterus and cervix appeared to be perfectly healthy.

One month later, October 25th, my notes of the case state that the diseased area had gradually diminished in extent, but the discharge continued without perceptible change in quantity or quality.

In the following month my notes convey the information that the fundus appeared to be free from disease, but that upon the interior of the body, there

¹ Read before the Boston Society for Medical Science, November 12, 1883.

far as could be observed, without the slightest effect upon the disease. As before remarked the uterus gradually lost its mobility, became larger, and in the middle of June firm adhesion had been made with the intestine into which an opening formed at a point in the fundus corresponding to that where the disease was first detected. The fæces now were discharged per vaginam. The strength began to fail more rapidly. Treatment was abandoned, and attention given only to afford the greatest comfort. Still there was no actual suffering in the way of pain, but she gradually sank from exhaustion, and died July 12th, within one month of two years from the time of my first visit to her, and two and a half years from the initial hæmorrhage. Permission was obtained, at the last moment, for a partial autopsy, and the portions removed were kindly examined by Dr. Cutler, whose brief report is as follows:—

"The vagina was smooth, and the rugæ gone. There were small ecchymoses on the surface of the mucous membrane. The color was rather slaty.

"The interior of the fundus and cervix uteri was one general sloughy mass of the same general appearance as the fragments previously examined. They were grayish, stinking, and evidently consisted of changed and infiltrated uterine tissue.

"The fundus was pretty generally destroyed, and but little of the wall was left. There was an opening into the rectum at the upper part of the fundus admitting four fingers. The tissues of the rectum at the edges of the opening were fungous, and on squeezing them there exuded a milky-white juice, as if issuing from a pepper-box. The bladder was healthy. The intestines were matted together and adherent over the surface of the uterus. No enlarged glands were found. Microscopically the disease was of a malignant nature."

I have taken pains to give the history of this case in detail, for it belongs to an interesting series of cases, few in number, which have been described from time to time as they have been observed within the last few years. In this instance I was enabled to follow the case closely, almost from its incipency to the end. In the main it corresponds very well with the description given by Goodell in his *Lessons in Gynecology*. Many of us are familiar with the so-called benign disease which has been designated by various names: endometritis hyperplastica, endometritis polyposa, fungous granulations of the endometrium, *fungosités intra-uterines*, etc., etc.

Another form of disease, malignant or quasi-malignant in its nature and history, has received the name villous degeneration of the endometrium, villous cancer, and papillary cancer of the uterus. I had under treatment a few years ago a case of this kind. In macroscopic appearances the case in hand bore a striking resemblance to that one of papillary cancer, when it was left to itself for a time, and the diseased mass growing most rapidly in the direction of the least resistance soon formed a tumor which projected within the cervix. Yet the microscopic examinations by Dr. Cutler could not ally the two cases. Sarcomatous degeneration too must be excluded, for throughout the case there appears to have been no evidence to place the disease in this class of tumors. Yet cases have been reported, where it has been a difficult matter, if not impossible, to decide with a given specimen whether or not it was sarcomatous. In the course of a discussion at a meet-

ing of the Obstetrical Society of Boston, as reported in the *Boston Medical and Surgical Journal*, October 10, 1878, Dr. Fitz remarked that he had been unable to distinguish these cases as being sarcomatous or not in one or two instances where he had examined specimens. At all events the affection has an element of obscurity about it, which makes each case of great interest. In the matter of diagnosis and prognosis I will venture to offer the opinion that if a woman previously healthy, especially if she be of full habit and bulky, *who has already passed the menopause*, has a hæmorrhage from the uterus, followed by a leucorrhæal discharge, and a proper and intelligent examination discovers nothing abnormal except granulation tissue, or hyperplasia of the endometrium, especially if there is found a papillary increase of all the tissues of the interior of the uterus, then, I say, we shall be safe in giving an unfavorable prognosis. The affection, if left to itself, will shortly develop into an evident malignant form of disease. If treated carefully, intelligently, and constantly, it will be recurrent, will invade the adjoining tissues more extensively in every direction, and eventually prove fatal, and yet in its microscopic appearance it may never furnish absolute evidence of either epithelioma, carcinoma, or sarcoma. I think a careful study of the cases already reported (and I know of no better description of them than is given by Professor Goodell in his work, to which I have already alluded) will enable one to coincide with me in this opinion.

As to the treatment of such cases I imagine there is a large field open for discussion in these days of wonderful successes in abdominal surgery. The histories of all recorded cases denote absolutely that something ought to be done to arrest hæmorrhage, to diminish or alter uterine discharges, so as to avoid bad odors and prevent septicæmia; in other words, life may be prolonged and made more endurable by means of the intelligent use of the curette and intra-uterine applications of various kinds, fluid and solid, styptic, alterative, caustic, escharotic, antiseptic, and deodorizing. Meanwhile, the digestive functions need to be kept in good order, and the general system will require constant tonic, perhaps stimulating, treatment. The question as to the advisability of the entire removal of the uterus will occur to every one. So far as I am able to judge from a pretty careful study of the cases reported up to the present time where the uterus has been removed, in one way or another, for malignant disease, it would appear that all might unite in expressing the opinion that cases such as I have related are just the ones where this operation is demanded; for they usually will be recognized early, when the disease is limited to a small area, the uterus is movable, unattached by adhesions to the adjacent organs and tissues, there is no glandular or systemic affection; indeed the disease, at least until the very latest stage, appears to be an uncomplicated, purely local affection, and yet experience teaches that it is sure to recur, *in situ*. I know of no case which will serve to indicate that a similar disease occurs elsewhere in the system in the same individual, though I have an impression that Dr. Baker, of this city, once mentioned a case to me where something of the kind appeared within the vagina of one of his patients, and this recurred repeatedly after removal with the curette. What was the exact nature of the affection in this case, or what was the final result, I am unable to state.

If I mistake not the opinion of the medical profession which now survives the glamor surrounding the brilliant surgical exploits of Freund and other, mostly German, surgeons, I think I may safely assert that Dr. A. Reeves Jackson, of Chicago, Ill., accurately voiced that opinion in his paper presented at the last meeting of the American Gynecological Society, wherein, in his final argument, he asserted that:—

“Extirpation of the cancerous uterus is a highly dangerous operation, and neither lessens suffering—except, in those whom it kills—nor gives reasonable promises of permanent cure in those who recover. Hence, it fails in all the essentials of a beneficial operation, and should not be adopted in modern surgery.”

But assuming that our knowledge of the natural history of the disease with which my case should be classed is sufficiently accurate, it would appear to be good practice under similar circumstances to advise an early resort to the radical operation for the removal of the uterus, before adhesions have been formed with adjacent structures, where the vaginal method could be employed with comparative safety, and the patient afforded every opportunity possible for permanent relief. Judging from the cases already reported, it appears to be the rule that they come under medical observation at a very early period in the development of the disease, differing in this respect from cases of true carcinoma or epithelioma; and, so far, they seem to suggest this as the proper mode of attack in the light of our present surgical experience.

RECENT PROGRESS IN PATHOLOGY AND PATHOLOGICAL ANATOMY.

BY WILLIAM F. WHITNEY, M. D.

ON SUPPURATION WITHOUT THE PRESENCE OF BACTERIA.

In order to answer the question whether pus could ever be formed independent of the presence of the micro-organisms, Councilman¹ instituted a series of experiments under Conheim's direction. A number of capillary glass tubes were sterilized by fire and then filled with a mixture of one part croton oil and five parts olive oil. These were introduced beneath the skin of the back of a rabbit. After the slight wound of entrance had entirely healed (the time for which varied from three days to two weeks) the tubes were broken subcutaneously. At the end of a few days an indistinctly fluctuating tumor could be felt, which upon extirpation proved to be full of pus. In this there was not the slightest trace of bacteria to be found. Other experiments, for the purpose of control, were made in an exactly similar way, only substituting a weak solution of common salt for the croton oil. The swelling which followed was firm, and upon examination bits of glass were found to be encapsulated by solid connective tissue. This of course does not prove that the infectious processes do not cause suppuration, but merely that other irritants than those furnished by bacteria can give rise to the same phenomena.

AN EXTENSIVE MYCOSIS OF ANIMALS.

Under the above title Wolff² has published his investigation of the cause of death of the large number

of gray parrots (*Psittacus erithacus*), yearly imported into Germany.

The clinical symptoms were first, loss of appetite, with at times complete disregard of food. The birds then became dull and moping, and their wings drooped. Soon diarrhoea set in; at first the faeces were thin and yellowish, but later mixed with mucus. There were six to eight stools daily and occasional vomiting of greenish yellow masses. With bristling feathers, and closed eyelids, the parrots cowered on the ground in a comatose condition. Towards the end convulsions appeared, in which the head was drawn down against the breast or under the wing, and in one of these spasms death occurred. Coryza, dyspnoea, cough, and râles, which, however, were not always present, pointed to a coincident affection of the respiratory tract. The course of the disease was from eight days to three weeks.

Anatomical appearances. No external wound of skin or mucous membrane. Heart and lungs with but slight changes.

Liver. Two dozen small gray or grayish white nodules shining through the serosa. On the cut surface the parenchyma was quite firm, bluish red in color, and studded with numerous grayish white nodules, denser than the surrounding tissue.

Spleen soft, bluish red, with numerous white foci in its midst.

Kidneys were hyperæmic, marked by small gray lines.

Mucosa of the stomach, pale, wrinkled.

Small intestines contained a large quantity of yellow watery material. *Mucosa* slightly swollen.

Sections were made from the liver, after having been hardened in alcohol, and were treated with concentrated acetic acid. The microscopic examination showed that in the midst of the whitish nodules there were yellowish brown lines, either straight or crooked, at times isolated, but more frequently anastomosing with one another in the form of a net-work. With a high power these resolved themselves into zooglæa masses or scattered micrococci. Staining with methyl, violet, gentian, or brown facilitated their demonstration. The same organisms were found choking the capillaries of the liver. Where they were present in the smallest numbers the walls of the vessel could still be distinguished as fine lines, bounded on either side by the bacteria, and containing with them numbers of red blood corpuscles stained in the same way as the parasite. In other places a thrombosis had extended for some distance along the vessels, which either were changed into thick bands or else, as was more frequently the case, they presented varicose enlargements. Similar plugs were also met with in the larger vessels, and finally in the midst of the liver tissue proper were free colonies, in the form of round or irregularly shaped balls, while in their neighborhood lay single scattered organisms, the form of which could be made out. This proved to be spheroidal, or occasionally more oval, so that the length (about one half millimetre) was twice as great as the breadth. These spheres were often united in pairs (diplococci) or in threes or fours.

The liver tissues appeared normal about the smaller foci, but near the larger ones marked changes were found. Here it was more transparent, and the columnar arrangement of cells was destroyed. Glancing cells (scales) devoid of nuclei, of a light yellowish

¹ Virchow's Archiv, Bd. xcii., s. 217.

² Virchow's Archiv, Bd. xcii., s. 252.

color, were seen in the place of the normal ones. No pus was noticed even about the largest centres.

The invasion of the lungs was extensive, although not so well marked as in the liver. In at least every third preparation thrombi of micrococci were present in the capillaries, some of which were dilated, and they were also seen lying free in the parenchyma of the lung. There was, however, no change in the tissue either in the form of necrosis or cellular infiltration; at most the collateral vessels were slightly fuller than usual. The alveoli contained a few cells in which were shining granules of unequal size. The greater part of the alveoli and bronchi were unobstructed.

In the spleen there were extensive deposits of micrococci, lying free in the parenchyma either as round or oval individuals, or united in short chains of threes or fours.

In the kidneys the parasites were found in the vascular system of the glomerulus, and in that surrounding the tubules. In various places the vessels had been perforated, and the micrococci were in the tissues or else occupied the tubules, which were distended by them.

The other organs, as well as the intestinal tract, were free from the presence of the organism.

In regard to the relation in which the bacteria stand to the economy of the animal, there are two cases to be considered. The first when they are present in small quantities, and are still separated from the glandular elements by the vascular walls. Under such conditions they do not need to enter into a struggle for existence with the surrounding cells, as they can easily receive a sufficient supply of nutriment. In the second case, where there is an extensive growth of the parasite outside of the vessels, the bordering elements give evidence of a marked pathological change, coming under the head of tissue necrosis. (Clear, glancing look, indistinctness of cell outline, and disappearance of the nuclei.) It is only after this has proceeded to a high degree that inflammatory (purulent) changes are manifest.

In the parrots this never reaches the inflammatory condition, which is rather remarkable, as in other forms of infectious disease (pyæmia, diphtheria, erysipelas, etc.,) this latter stage is found associated with the slightest changes of the affected part.

The ætiological factor is to be sought in the crowded and ill-ventilated cages in which the birds are kept during the passage. The point of entrance for the parasite is probably the lungs.

Of the other mycotic processes with which birds are troubled (splenic fever, ulcerative endocarditis, diphtheria) the *cholera des poules* of Pasteur is the only one with which it would be likely to be confounded on account of its clinical symptoms. In the last named disease, however, the pathological changes are entirely restricted to the intestines, which are uninvaded in the disease under consideration.

In epidemics it is of the greatest importance to look for the source of infection not only in man himself, but also in the household animals, which are found to suffer from the same infectious diseases that he does. Attention has already been directed to the larger animals, but as yet little attention has been paid to birds. The ways of infection of man are so much enveloped in darkness as yet that it is of the utmost importance to be careful with household pets, like the gray parrots, which so often suffer from mycotic disease.

THE MICROCOCCUS OF PNEUMONIA.

Ziehl¹ has given an account of the micrococcus which he has found in the sputum of patients suffering with pneumonia. Klebs was the first to call attention to the occurrence in lungs, and his observations were corroborated by Eberth, Friedländer, and Koch. The organisms which were found in the cadaver were of an ellipsoidal shape, their length about one millimetre, with a breadth of one third less. Round forms also occurred, joined together as diplococci or in short chains. In the fibrous plugs filling the bronchioles they appeared as flat masses which were in close proximity to each other. This post-mortem discovery was confirmed by Leyden, who obtained them from the living subject by means of direct aspiration of the lung.

The parasites discovered by the author in the sputum corresponded with those already described; they were only found pure in the earlier part of the disease, while in the later stage, especially near the crisis, they were mixed with a variety of other forms. Preparations were made by drying the sputum on a cover glass and staining with gentian violet.

In all cases where they were found the disease was considered to be of the infectious type. Their presence may possibly be of value in determining whether there are two types of pneumonia. As, for example, the pneumonia which follows contusions of the chest is considered by some authors as being simply an extension of a pyæmic process inwards, while others, among them Ziehl himself, regard the trauma as simply furnishing a proper soil in which the specific organism can develop.

MICROCOCCUS OF GONORRHOEA.

Eschbaum² has given the following method for demonstrating this form of bacteria. A little of the discharge is dried upon a cover glass by rapidly passing it through the flame of a spirit lamp three or four times. It is then allowed to float with the prepared slide down for fifteen to twenty minutes in a watery solution of gentian violet, afterwards placed for a few seconds in absolute alcohol, dried over a lamp, and mounted in Canada balsam.

A CONTRIBUTION TO THE PATHOLOGY OF OLD AGE.

This has been the subject of an article by Somerbrodt,³ from his experience in the Pensioners' Hospital at Berlin from 1873 to 1877. Twenty-five autopsies were made on men over seventy years of age. Acute disease, as has been generally noticed, occurs but rarely, and when present is generally connected with the organs of respiration. The heart was affected in but few cases, while in every case evidences of endarteritis were to be seen. Chronic inflammatory changes were frequent in the meninges, while hæmorrhage into the substance of the brain was rare. Gall stones, which in extreme old age never caused colic, were found in eight cases. Malignant disease (cancer of the prostate) presented itself but once. The course of such troubles is probably run in previous decades. Pleural adhesions were often met with, but exudation into the pleural cavity very seldom.

In about one half the cases tubercles, that is, cheesy

¹ Centralblatt f. d. med. Wissensch., 1883, s. 434.

³ Centralblatt f. d. med. Wissensch., p. 601.

centres, were scattered throughout the lungs, and this was notably oftener the case in persons who were quartered together in barracks than in those who had a separate dwelling. This fact, the author thinks, points to the contagiousness of the disease. In general its course was run almost without symptoms; especially was it to be remarked that hæmoptysis was absent in the majority of the cases.

THE MANNER OF ORIGIN OF THE ANENCEPHALIC FŒTUS.

Ribbert¹ has encountered two fœtuses in animals which give a clew to the way in which this malformation originates.

Three theories have been proposed in explanation of this: (1) pressure upon the skull of the embryo by the amnion, and a union of the two; (2) early hydrocephalus which prevents development of the brain, and which ruptures before birth (this is the one generally accepted); and (3) an extreme bending of the anterior end of the embryo at a time when the spinal column exists as a furrow or has only just closed over.

The cases described apparently point to hydrocephalus as the most probable cause. One occurred in the embryo from a goat and the other from an ox. In neither case was there a union of the amnion with the skull, nor did the cord present any abnormality.

On the top of each head was a longitudinal defect in the cranium, surrounded by a slight wall about one millimetre high, recalling the ruffle of a shirt. On one of the specimens this was divided by a transverse septum into an anterior and a posterior portion, from which led two openings into the interior of the head. Through the posterior a bristle could be passed for some distance towards the bend of the neck, while anteriorly it soon met with an obstacle. From the overhanging edge of the wall shreds of delicate membrane floated. The length of the defect was about five millimetres, and its breadth to its length as two to three. The second embryo presented a similar condition, only the septum was not so well marked between the two openings, and the anterior opening was spanned by a very thin membrane, leaving a space the size of a needle between it and the posterior wall. The figures given in the text show clearly that there has been a defect in that part of the skull covering the middle cerebral portion and caused by an accumulation of fluid within (hydrocephalus).

ON THE PATHOLOGY OF ASTHMA.

Riegel and Edinger² investigated whether asthmatic attacks, especially those in which an emphysema was rapidly developed, were produced by cramps of the bronchi (Biermer) or by spasm of the diaphragm (Wintrich). First they proved the capability of the bronchus for contraction. They found, in accordance with the experiments of earlier observers, that the unstriped muscle of the air passages could be excited to contract by irritation of the vagus. The amount of spasm caused in this way, however, was very small. Long-continued stimulus, however, produced emphysema.

If the vagus was cut and the peripheral cut end excited the emphysema did not take place, but only by

acting upon the central end. Therefore it followed that this did not depend upon a narrowing of the bronchi from direct irritation through the vagus, but a reflex irritation of the inspiratory tract from the vagus. Further it was found that after section of the phrenic nerves, irritation of the vagus was followed by no distention of the lungs.

The authors think that the emphysema of asthma is the effect of a reflex diaphragmatic cramp. In proof of this they show that over distention of the lungs could be produced by irritation from the inhalation of ammonia gas so long as the vagus was uninjured. Yet they are not of the opinion that spasm of the midriff alone is capable of explaining all the features presented by asthma.

ON THE RENAL CIRCULATION DURING FEVER.

Mendelson³ has studied the variations in the size of the kidney by means of an ingenious apparatus called the oncometer, or bulk measurer, designed by Conheim and Roy.

The kidney is first exposed by cutting through the muscles of the back in the lumbar region, and carefully tying all the small vessels. It is then brought out through the wound and placed in the machine, which consists, briefly, of a double box, the inner wall of which is made of the peritonæum of a calf, and the outer of thin brass. The space between the walls is filled with olive oil, and connected by means of a tube with a kymograph, upon which any variation in the size of the organ can be recorded.

In dogs in which complete motor or sensory paralysis or both had been caused by narcotics there was found to be a marked fall of temperature. In order to obviate this, insensibility was produced by puncture of the thalamus. The skull was trephined about five millimetres on either side of the median line, at the point of greatest cranial convexity, about four to five centimetres in front of the prominent occipital tubercle. A small slit was made in the dura mater, and a blunt glass rod, about two centimetres in diameter, was pushed directly downwards towards the base of the skull till it struck the bone. Animals thus operated upon were rendered insensible and motionless, and pyrogenic agents caused a marked rise in temperature.

The substance used to cause this was pepsin, five grammes of which, dissolved in fifty cubic centimetres of water, were injected into a vein. With the advent of the fever there was a diminution in the size of the kidney. This could also be effected by surrounding the carotids, which had been laid bare, with hot water. From these experiments he concludes that the decrease in bulk of the kidney during fever is due to contraction of its vessels, probably resulting from a stimulus conveyed to them from the central nervous system, — this stimulus being in consequence of irritation of the central vaso-motor centres by the abnormally hot blood circulating through them during the fever; and in addition he found that the contraction is constant and progressive, being proportionate to the intensity of the fever.

This anæmia of the kidney he thinks explains satisfactorily the diminution in the quantity of urine, and also the albuminuria; the albumen being allowed to pass through the epithelium of the glomeruli, which, having been insufficiently nourished by the small supply of arterial blood, loses its albumen-retaining power.

Reports of Societies.

PROCEEDINGS OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M. D., SECRETARY.

NOVEMBER 12, 1883. DR. CHARLES D. HOMANS presided.

DR. FRANCIS MINOT reported

A CASE OF HERMAPHRODITISM.

The patient was nineteen years old, and had always been supposed to be a female. She was tall, bony, and had a deep bass voice. The breasts were not developed, and there had never been any menstruation. There was no beard. There was an enormous clitoris resembling a glans penis, having a prepuce which was easily retracted, and which was fissured at the lower part, looking like a case of circumcision. There was a depression at the usual situation of the urethra in the glans, but no true meatus, which was situated below the clitoris as in the female. Below this was the vagina, two inches in depth, and partially closed by a hymen. Neither uterus nor ovaries were found. There was a swelling in the left labium when the patient strained, which was apparently a hernia. There was no sexual feeling, and the patient appeared to have no preference for the society of either sex.

DR. W. W. GANNETT stated that in a recent number of the *London Medical Record* are accounts of twelve or fifteen similar cases taken from Russian sources.

DR. W. E. BOARDMAN reported

A CASE OF MALIGNANT DISEASE OF THE UTERUS.¹

DR. WM. H. BAKER spoke of the interest attaching to this exceedingly rare class of cases; the disease, situated within the uterus, having the general microscopic appearance of benign disease, but frequently recurring and becoming malignant. So far as he knows none like it have been reported. In one similar case of his own he dilated and curetted the uterus. Six months later disease appeared on the cervical membrane. This looked like hypertrophied utricular glands, although the utricular glands proper are in the body of the uterus. He tried cutting away the neighborhood of the canal, but this was followed by contraction partially occluding the os. In a few months there was hæmorrhage. He then dilated and used the sharp curette and nitric acid. This was followed by pelvic peritonitis. The patient recovered, and disease next appeared on the vaginal wall. He now used the sharp curette and the actual cautery, and this was repeated for the same cause two or three months later. A year after, the hæmorrhage returned, when he examined and found the body large. There is no disease in the vagina and none in the cervix as far as can be seen, but there is little question as to the body. In a second case which is now under observation, he has twice thoroughly removed the diseased tissue with a sharp curette. The last operation was five or six months ago, and the patient now seems to be doing well.

He would agree with Dr. Boardman that having hæmorrhage occurring after the menopause, together with activity of any growth removed from the uterus, however benign it might seem to microscopic examination, the only hope for the patient is in removal of

the uterus. The operation would be more hopeful than in cancer, and he would give the patient the chances. He would not be understood as condemning removal of the uterus for cancer, although in that disease, as it will return, if it is limited to the cervix, he thinks there is a safer operation.

DR. J. G. BLAKE remarked that he had had no experience in treating malignant disease of the uterus such as had been reported, his cases having been confined to the cervix and not extending to the body of the womb. An important point in the diagnosis, and upon which gynecologists laid great stress, was the value of hæmorrhage occurring after the climacteric and where there was an absence of fibroid or other cause for it. Some writers insist that this alone is an unfailing indication of malignant disease, even when the microscope, as in this case, did not corroborate it in its early stage.

In relation to the treatment, he was decidedly in favor of recommending the removal of the entire uterus rather than to trust to the unsatisfactory local treatment, which in all cases thus far reported has terminated fatally. In these days of brilliant success in abdominal surgery, and in the light of recent operations reported to this Society, he could not but think that the time was near at hand when the radical operation would be more freely resorted to, and with better success than had thus far attended it. The difficulties are not greater than in many of the ovariectomies complicated by adhesions, and while the shock attending the removal of an important organ like the uterus might be more severe, he felt that the invariably fatal result under present methods of treatment would justify the operator in taking the greater risk.

DR. C. M. GREEN said that, in the opinion of some men, giving a bad prognosis to the patient in a case of cancer, or even telling the patient herself that she has cancer, is liable to react very unfavorably upon the disease. He would like to ask the opinion of the Society as to our duty in the matter of prognosis.

DR. G. H. LYMAN said it must depend on circumstances, including the character of the patient; some will bear such news with equanimity; others will not. He prefers to tell the friends, and leave the matter to their judgment; but if the question is asked by the patient the truth should be told gently and considerately, provided the physician's own mind is fully made up.

He believes that removal of the uterus will be more and more successful, and that the operation is destined to rank with ovariectomy. Although some Continental statistics have been very bad, yet Dr. Keith has published some nine or eleven cases, all that he has had at the Edinburgh Infirmary, and with uniform success. It is true that most of these were for fibroid tumor, but Dr. Lyman does not see why in malignant disease an early operation would be less successful as an operation. The liability to recurrence of disease in neighboring tissues is a separate question. He doubts if the curette or partial removal by the knife will be of any more service than caustic washes, and believes that neither of them do more than give temporary relief. If any serious operation is to be done the entire removal of the uterus would seem to be the only procedure to follow, and even that so far, presents little encouragement as to ultimate success.

DR. R. H. FITZ referred to the post-mortem examination of a case of diffused cancer of the body of the uterus whose clinical course resembled that described

¹ See page 488 of this number of the JOURNAL.

by the reader. The patient was between thirty and forty years of age. The immediate cause of death was a thrombosis of the cerebral sinus, due to the marasmus resulting from the long-continued, profuse, watery, and hæmorrhagic discharge from the uterus. The condition of this organ illustrated the difficulties in making a diagnosis from the microscopic examination of scrapings from the uterine cavity. It also explained the inefficiency of the usual methods of treatment in producing a radical cure. The uterus was enlarged to the volume of the two fists. Its wall was of moderately increased thickness, but its cavity was greatly distended, readily containing the fist. The inner surface was covered with partially decomposed shreds of soft, friable tissue, in part adherent, in part readily floating in a stream of water poured upon the organ. After the detachment of these shreds the muscular substance of the uterus was found trabeculated, suggesting the ventricular walls of the heart or a specimen of trabecular hypertrophy of the bladder. The new formation extended into the uterine wall, burrowing its way between the muscular bundles, dissecting them out, and closely approaching the peritoneal surface.

The customary treatment of such cases obviously affects merely the surface, not the diseased substance of the uterus, and no radical treatment can be of avail which does not include the removal of the organ as a whole.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

C. B. NANCREE, M. D., RECORDER.

THURSDAY evening, October 25, 1883. The President, DR. TYSON, in the chair.

DR. SEILER read a paper on the Pathology of Phthisis and its Laryngeal Complications, in which he gave his views regarding the pathology of tuberculosis and of phthisis and of the laryngeal complications of the two diseases. He defined tuberculosis as an auto-infectious disease, manifesting itself primarily by the production of minute neoplasms called miliary tubercles, which rapidly undergo retrograde metamorphosis, ending in caseation, being due to the dissemination of infectious material throughout the lymph channels. This infectious material consists in cheesy matter, due to scrofulous inflammation, which may remain incapsulated for a long period. He then described the histological characteristics of tubercles, and showed how they could produce consolidation of the lung tissue by exciting secondary inflammation.

The doctor then entered upon the consideration of the disease known as phthisis, and gave the following definition of it: Phthisis is a progressive consolidation of the lung tissue, due to a more or less localized inflammation, affecting primarily the apices, and undergoing retrograde metamorphosis; it is an inflammatory disease. He then gave a description of the pathological processes, as they are observed in the lung tissue during the progress of the disease, and gave it as his opinion that the different forms and stages of phthisis, as they are described by many authors, are merely differences in the severity and extent of the ulcerative process. As ætiological factors he mentioned the various causes which produce a lowering of the vitality of the general system, thereby producing a predisposition on the part of the respiratory organs to chronic inflammation. Among others, he named heredity, peripheral nerve irritation, hypertrophic nasal catarrh,

insufficient aëration of the blood, etc. An elevation of the vitality of the system at large would prevent an outbreak of the disease or lead to recovery in cases where not too much lung tissue had been destroyed. This elevation was to be produced by proper feeding and healthful exercise in the fresh air more than by the exhibition of drugs. On the other hand, tuberculosis was always fatal, and treatment was of no avail; but a great deal could be done to prevent the formation of the initial formation of the cheesy deposit by elevating the system of scrofulous patients early in life, thus preventing the outbreak of tuberculosis later. The laryngeal complications of both diseases were then considered in detail and their differences pointed out. So, according to the lecturer, the laryngeal lesions never appear prior to the lung disease in phthisis; they are characterized by a peculiar pallor of the mucous membrane; the tumefaction generally affects the posterior portion of the organs, and the ulcerations are shallow and have a tendency to spread on the surface. Tubercles or cheesy deposits are never found in the tissues of the larynx in phthisis. In tuberculosis, on the other hand, tubercular deposits have been found in the larynx prior to the lung complication, the mucous membrane is of a livid red color, the tumefactions are more commonly observed in the anterior portions of the larynx, and the ulcerations are deeper, with raised edges, and often extensive destruction of tissue.

The paper closed with the remark that the indiscriminate use of the terms phthisis and tuberculosis when speaking of lung diseases in our literature was calculated to mislead the student and make careful investigation into the pathology and ætiology of these diseases extremely difficult if not impossible.

DR. J. C. WILSON being called upon by the President, said that he had listened with interest to the reading of the paper. The field covered by the writer is too great to permit the points to be discussed in detail. Two points, however, appeared to warrant comment. First, Dr. Seiler had several times used the expression, "tuberculous material not derived from the exterior." If he had understood the paper aright, Dr. Seiler had not indicated his views as to the nature and source of this "tuberculous material." Does he follow the older doctrine, that of Baker? or has he some new opinion as to the ætiology of tubercle? Secondly, Dr. Seiler failed to make clear his means of recognizing tubercle, either clinically or in the laboratory. It would be of interest to hear the writer's views upon this vexed question. In a recent work, Hamilton of Aberdeen again seeks to establish a histological criterion for tubercle — the presence of giant cells under a peculiar arrangement. This pathologist points out two modes of degeneration for tubercle: (1) caseous; (2) fibroid. To the latter Dr. Seiler makes no allusion.

He thought further that the author of the paper had scarcely emphasized with sufficient force the presence of tubercle among the lesions in the various forms of phthisis as seen in post-mortem examinations.

He heartily concurred in the hopeful views as to the curability of certain forms of chronic lung disease when treatment is instituted at an early period. Nothing has exerted a more unfavorable influence upon the therapeutics of such diseases than the false view that the constitutional tuberculous diathesis invariably antedates the local lesions of pulmonary consumption.

DR. F. P. HENRY remarked that Dr. Seiler's paper was so comprehensive that he found it impossible to

refer to more than a few of the points contained in it. He was not inclined to draw so broad a line of distinction between that form of pulmonary disease in which miliary nodules predominate and that in which the deposit is in larger caseous masses. Like Dr. Seiler, he was by no means convinced of the primary importance of the bacillus as a cause of tuberculosis, but was inclined, however, to attribute to it a prominent part in the production of the secondary symptoms of phthisis, those of systemic infection, which are largely septic in character. The symptoms of interference with oxidation caused by even extensive destruction of pulmonary tissue are subordinate to those of systemic infection caused by absorption of the contents of cavities. The presence of the bacillus in the contents of these cavities is indispensable to the production of changes capable of producing this systemic infection. A small ulcerating cavity communicating with the absorbent vessels is more disastrous in its effects than a larger cavity shut out from the absorbents by a lining membrane or wall of fibroid tissue. He understood Dr. Seiler to deny the existence of the giant cell and to make the statement that cross sections of blood and lymph vessels have been mistaken for it. Dr. Henry did not agree with him in this view, but thought the irregular contour of the giant cell and its granular protoplasm were sufficiently characteristic. Additional evidence of the existence of this cell was furnished by the experiment of introducing beneath the skin of an animal two thin glass covers fastened together. In the interspace of the glasses giant cells have been found, and in such an experiment there can be no question of the cross section of vessels. Dr. Seiler had several times referred to what is known in this city and elsewhere as Formad's theory of tuberculosis, which is that in certain animals predisposed to phthisis, and presumably in some human beings, the lymph spaces are abnormally small, or, in other words, that in a given area of tissue there is to be found a greater number of endothelial cells than in non-strumous animals. Dr. Henry did not think this theory should be so extensively quoted until some more serious attempt had been made to establish or refute it. This might, he thought, be readily done by counting the cells in a given area of the tissue of strumous animals and comparing their number with that contained in the same area of tissue of non-strumous animals. He did not think any greater difficulty would be met with in this attempt than has been successfully encountered in the enumeration of the blood cells.

Dr. BRUEN said that he believed in a hopeful prognosis in the early stages of many varieties of phthisis; even when the process of phthisis was advanced, the management of cases was more successful when the lesions are localized; less advanced lesions are more grave when the lesions are widely disseminated. Dr. Bruen thought that it had been proven that phthisis could be produced by inhalation of inorganic irritating particles, especially if there was inherent predisposition to phthisis, or an artificially damaged constitution. May not bacterial elements be among the irritants capable of developing phthisis, when inspired in large numbers, and he thought they might be even more capable of creating damage than inorganic materials, because they possessed the power of proliferation. Dr. Bruen agreed with Dr. Seiler in his views in the main, and considered his paper most instructive and interesting.

Dr. MILLS thought it worth while to note the frequent occurrence of tuberculosis among those afflicted with chronic nervous and mental diseases. At the institutions for the Feeble-Minded and Insane phthisis or tuberculosis is a common cause of death. This fact he thought would lend support to the views of Formad rather than to those of Koch.

Dr. J. T. ESKRIDGE had observed that some who had participated in the discussion referred to the views of the pathology of tuberculosis expressed in the paper of the evening, and to those entertained by Dr. Formad, in order to prove the same thing. He regarded the theories of each of these men as widely different. If tuberculosis is the result of inflammation in a person whose lymph channels are abnormally narrow, as claimed by the latter, he could not see that phthisis differed from tuberculosis as maintained by the former. In regard to tuberculosis being frequently developed in chronic diseases of the brain and cord throwing light on the pathology of the former, he thought the association of these diseases proved nothing more than that a prolonged period of lowered functions of the body was a favorable condition for the development of tuberculosis. He confessed that he did not know what to believe with reference to the pathology of tuberculosis; enough, to his mind, had not been proved to firmly establish any theory yet advanced, so that it might be accepted as positive fact. Dr. Eskridge agreed with Dr. Shakespeare in demanding more pathological investigation following the clinical observation of the disease before he could accept any view as positive of the pathology of tuberculosis. Dr. Eskridge called attention to the fact that many of the best clinical observers of large experience, such as Flint, Da Costa, and Hughes Bennett, considered tuberculosis and phthisis to be identical.

Dr. DAVIS asked Dr. Seiler if he taught that tubercle was caused by a caseous focus? He was answered, Yes. It is important to know whether this is the case or not, as the German surgeons excise caseous glands not so much for the deformity they produce as to obviate the liability to general infection. Would Dr. Seiler sanction this practice? As regards the possibility of cure he believed with Koster, Billroth, and Koenig that tubercle is a local affection, and not a general disease. He has seen as marked tuberculosis in the knee as in the lung, the miliary tubercles being within an eighth or quarter of an inch of each other. He has also seen tumor albus of the knee recover without operation. If the tuberculosis can get well in the knee he believes that it can, in some cases, get well in the lung also.

NEW YORK ACADEMY OF MEDICINE.

THE DEATH OF DR. SIMS.

At a meeting of the Academy held November 15th the Statistical Secretary, Dr. F. V. White, announced the death of Dr. J. Marion Sims, and the President, Dr. Fordyce Barker, made, with much feeling, a brief eulogistic address, in which he said that in the death of Dr. Sims the Academy and the profession not only of New York but of the whole country had lost its most brilliant and original genius in surgical gynecology. This was conceded by all, and no one was anywhere to be compared to him, with the exception, perhaps, of

the late Sir James Y. Simpson. He had been intimately acquainted with both these two eminent men, and he thought that they possessed much in common; their resemblances being much more marked than their dissimilarities. To speak only of the chief work of each, the one had secured enduring renown by his courage and ardent zeal in the successful introduction of anæsthetics for the relief of the agonies of parturition, and the other in the device of new methods of physical exploration and surgical procedure. Both were incessant, zealous workers, who for many years were continually making contributions of positive value to medical knowledge; the former adding more to scientific literature, and the latter more to the practice of our art. Dr. Barker then announced that he would appoint Dr. T. Addis Emmet to read a memoir of Dr. Sims before the Academy in January next.

(To be continued.)

Medical and Surgical Journal.

THURSDAY, NOVEMBER 22, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY, No. 4 PARK STREET, BOSTON, MASS.

SUPPLEMENT, CONTAINING THE REPORT AND PAPERS ON PUBLIC HEALTH, TO THE FOURTH ANNUAL REPORT OF THE STATE BOARD OF HEALTH, LUNACY, AND CHARITY OF MASSACHUSETTS, 1883.

AFTER the old Board of Health was swallowed up in the present triune Board, the old Health Reports, which had contained so many admirable papers on various important hygienic questions and are still referred to as authority at home and abroad, were continued for two years under the present title of Supplement to the Report of the Board, the last one appearing in 1881, and being for the year 1880.

Charity and Lunacy, however, were too many for Health, and the present volume appears after an intermission of two years, appropriations having been delayed.

All the papers in this volume, except that on Leprosy, by the Health Officer, Dr. Abbott, have been ready for publication for more than a year. The paper by Prof. S. P. Sharples, on the Adulteration of Food and Drugs, was originally prepared when the desirability of submitting a bill to the Legislature for the prevention of adulteration was under consideration. The Legislature eighteen months ago passed such an act, placing its execution and an appropriation therefor of \$3000 with the Board, which drew up a series of rules based upon the recommendations of the National Board of Trade, and appointed an analyst of food and

an analyst of drugs. Professor Sharples' contribution to the report is a concise, unsensational statement of questions relating to his subject, which a fifteen years' general acquaintance with it and special experience as a private analyst have qualified him to make. He states his belief "that, outside of the single article of milk, injurious adulteration is by no means common, and fraudulent adulteration is but little more common than injurious adulteration." This latter part of this statement, however, it seems to us, can hardly be regarded as accurate until every package of mixed goods is made to exhibit a statement that the article is mixed, as is now the law in England. The analysts appointed by the Board actually entered on their duties about a year ago. We have as yet seen no published report of their results, nor have there been any prosecutions, although we believe several are now pending against vendors of adulterated drugs and milk. The analyses of milk samples, we understand, showed the adulteration of this important article of food to be so extensive that an additional appropriation of \$2000 was found desirable, and made by the last Legislature for the execution of the Act of 1882 against this one article alone. The detection, exposure, and prosecution of offenders against any act for the protection of food and drugs are attended with many difficulties, not the least of which consists in the fact that the very consumers in whose interest the government analyst or inspector labors are found, not seldom, to side with the dealer against whom it is sought to shield them, resenting the imputation that they are not able to manage their own affairs and buy their own food. It is only by much practical experience with the working of such laws that the best forms are reached, and after all her legislation upon the subject of adulteration, the operation of present laws in England is still found quite unsatisfactory.

Dr. Jeffries, in a paper on our Eyes and our Industries, discusses a very important subject in a vigorous manner, and sets forth some of the causes which tend to produce defective eye-sight among the scholars in our schools. Apropos of the poor paper and type used in making school text-books, a résumé is given of Dr. Javal's Physiology of Reading, in which examples are given of various kinds of type in actual use, and of ideal type as it should be. This part of the paper certainly appeals to all readers and printers.

The paper on Leprosy by the Health Officer of the Board, Dr. Abbott, is a compilation, with a bibliographical appendix, of the substance of the most recent contributions to the history, symptomatology, and mode of propagation of this disease, and was suggested by the recent appearance of a case at the Salem almshouse in the person of a former citizen returning from the Sandwich Islands via San Francisco. Another probable case of leprosy is, we believe, now under observation at Tewksbury. Such steps have been taken at San Francisco as to render the entrance of any more leprosy from the Sandwich Islands very improbable, but the Norwegian immigration continues a source of possible danger.

A considerable portion of the report is occupied by

the tabulated returns from seventy-one water boards and water companies throughout the State, received in response to a second circular sent out by the Board in compliance with an act of the Legislature passed in 1879 requiring all such boards and companies to make triennial reports. A uniform table will probably be required in future for water analysis for the sake of convenience in the comparison of waters of the State with each other, as well as with those of other States and countries.

A short and suggestive contribution from Mr. Ernest W. Bowditch on The Sewerage of Nahant, which should be read in connection with a previous paper by him on The Sanitary Aspect of Nahant, completes the volume.

The Health Officer devotes a few pages of the General Report to some remarks on Commercial Fertilizers or Artificial Manures. The regulation of manufactories of these products is a somewhat delicate though very necessary and urgent matter, the ultimate decision of which can hardly be left with safety in the hands of local boards of health as these are still too often organized, even in this State. Further legislation on this subject is desirable, as was well illustrated by the failure of the State Board in its attempt to regulate the works of the Standard Fertilizer Company, situated at the foot of Captain's Hill, near Duxbury. In this case the local board lent its countenance to the Fertilizer Company, and the local jury, to whom was the ultimate appeal, also found its sympathies enlisted on the side of the company.

We make the following extract from the report touching this subject:—

"The manufacture of chemical fertilizers or artificial manures has increased rapidly within the past twenty-five years, and assumed an important place among the industries of the State.

"The United States Census Report, 1880, gives the following figures relating to the manufacture of commercial fertilizers in Massachusetts:—

Number of establishments	21.
Capital invested	\$1,738,150.
Number of hands employed	570.
Value of products	\$2,164,680.

"The value of such works in contributing to the agricultural resources of the State cannot be questioned, and their maintenance should be encouraged as a useful and valuable industry. At the same time the processes of manufacture should be so guarded and restricted as to render them as inoffensive as possible to their surroundings by the choice of a suitable location of the works, and also by the adoption of such measures as shall remove as much as possible all offensive odor from the works resulting from the storage and handling of crude materials, the processes of manufacture, and the final disposition of the manufactured fertilizer.

"These points have already been referred to in previous reports of this Board, and the measures therein suggested have been complied with by several of the larger establishments in Massachusetts with manifest success. Water-towers, condensing shafts,

and the destruction of offensive gases by fire, have been employed in a satisfactory manner, and similar measures should be required of all establishments of the same sort, for wherever the work is carried on in the neighborhood of dwellings complaints are likely to become frequent from parties to whom the odors evolved may prove offensive.

"The act which concerns such trades and occupations provides that the State Board of Health, Lunacy, and Charity may order the persons or corporations to cease and desist from such business 'if, in their judgment, the public health or the public comfort and convenience shall require.' It is not necessary to measure the degree of offensiveness of noxious trades by the standard of the robust laboring man, especially if he is an employee in a factory of this sort.

"A charge of nuisance to public health is tenable when a considerable number of persons, whether invalids, persons of a delicate organization, or even such as are in perfect health, are so affected that their lives are rendered uncomfortable."

REGISTRATION REPORT OF MASSACHUSETTS FOR THE YEAR 1882.

THE forty-first report of the Births, Marriages, and Deaths in Massachusetts, edited by Dr. Frank Wells, shows, for the year 1882, the lowest birth-rate but one recorded in the State, the highest marriage-rate since 1874, a little less than the average death-rate, and a rate of excess of births over deaths of 4.62 to 1000 of the estimated population (1,921,179) as compared with a rate of 7.78 for the thirty years ending in 1880.

The living births, 47,155, give a birth-rate of 23.76, as compared with 28.88, 29.52, 25.36, 26.07, 27.62, 24.75, the averages for six quinquennial periods ending in 1880. The birth-rates for the year varied from 29 in the cities of 40,000 inhabitants and over, in a descending scale, to 16 in the towns with a population of less than 1000.

The ratio of males to females born during the year was 104.3 as compared with 105.7, the average for twenty-nine years. Of the 1485 still-births, the males were 147.7 to 100 females.

The illegitimate births were 865, of whom 482 had native-born, and 334 had foreign-born, mothers. In twenty years the rate of reported illegitimate births to all births has doubled. In 1882, 50.75 of the illegitimate births were in Suffolk County, containing our one large city.

The percentage of births of native parents and of mixed parentage, has been increasing; those of foreign parents, increasing from 1859 to 1871, have been since 1871 diminishing.

The 17,684 marriages recorded indicate 18.4 persons married to each 1000 of the population. The rate for the sixteen cities, with a population of 873,605, by the census of 1880, was one third greater than that for the rest of the State with 909,480 inhabitants.

The percentages of marriages by seasons was quite near the average, being, in order, 20.45, 25.98, 21.70, 31.87. The average age at marriage was 29.2 for men and 25.4 for women; of first marriages only, 26.5 for men and 23.9 for women. Fourteen thousand one hundred and eighty-two bachelors married maids, and 795 married widows; 1774 widowers married maids, and 845 married widows. There were 2689 widowers married, and 1710 widows. Thirty-seven and nine tenths (37.9) per cent. of the males were married between the ages of twenty and twenty-five; 30.8 per cent. between twenty-five and thirty; 13.3 per cent. between thirty and thirty-five. Forty-five and nine tenths (45.9) per cent. of the females were married between twenty and twenty-five years of age; 21.3 per cent. between twenty-five and thirty; 16.8 per cent. under twenty; 7.5 per cent. between thirty and thirty-five. Six hundred and seventy-nine men and 206 women were married over fifty years old; nineteen men and one woman over seventy-five, and three men over eighty. The marriage-rates indicate an increase in the marriage of natives with foreigners, the proportion having nearly doubled in twenty years.

The deaths registered in 1882 were 36,785, an increase of but 327 over the mortality of the preceding year, and 1493 over that of 1880. The death-rate per 1000 of the living population (19.14) was .38 per cent. less than the rate in 1881 (which in turn was .27 per cent. lower than that for 1880), .06 per cent. less than the average for the five years, and .11 per cent. lower than the average for the thirty years, previous to 1881. The mortality of children under the age of five was the lowest since 1872, and 3.83 per cent. less than the average for eleven years. With the decline also in the number of deaths from the "zymotic" diseases, the year must be considered as one of above the average health.

The sixteen cities have a death-rate one sixth greater than that of the rest of the State. The seasons showed a relative mortality in order of 24.14, 24.10, 28.67, 23.09, as compared with averages for twelve years of 24.2, 22.8, 29.4, 23.6. For the last five census years the average death-rate of males was 20.52, of females 19.28.

During the year 778 more males than females died under the age of five. Above the age of twenty, and particularly between twenty and thirty, the mortality of females predominated over that of males, as was the rule for the previous ten years; 20.22 per cent., or about one fifth of the total mortality, occurred under one year, and 31.23 per cent., or not quite one third, under five, — a proportion which is verified by the statistics of a period of years.

With 327 more deaths in 1882 than in 1881, there were 708 fewer deaths of children under the age of ten, and forty-three fewer between the ages of ten and fifteen. At all other ages, the number of deaths was greater. In the last census year (1880) the number of living persons recorded at the various ages was, under one, 37,587; under five, 179,307; from five to ten, 171,595; ten to fifteen, 161,425; fifteen to twenty, 167,595; twenty to thirty, 343,701; thirty

to forty, 264,413; forty to fifty, 203,515; fifty to sixty, 142,053; sixty to seventy, 91,619; seventy to eighty, 44,337; eighty and over, 13,525. The corresponding death-rates for that year were 191.28, 68.11, 8.52, 3.78, 6.58, 9.51, 10.29, 11.71, 17.86, 33.87, 73.14, 184.02.

The total death-rate from infection-diseases was less than for any of the previous ten years, the variations from year to year being shown in the following table: —

Years.	DISEASES.									
	Dysentery.	Typhoid Fever.	Whooping-Cough.	Croup.	Diphtheria.	Measles.	Scarlatina.	Cholera Infantum.	Small-Pox.	Total.
1872	564	1708	363	490	273	428	1377	8254	1029	9471
1873	485	1408	264	435	310	180	1472	2553	668	7723
1874	868	1147	449	411	602	161	1282	2322	26	6766
1875	437	1059	242	680	1200	233	1694	2608	84	8175
1876	417	881	192	684	2610	47	1223	2037	31	8171
1877	580	814	369	544	2634	135	467	1927	26	7496
1878	602	679	400	583	1934	805	404	1673	2	6482
1879	372	637	302	559	1734	19	850	1349	8	5330
1880	395	882	230	625	1789	236	574	2118	38	6367
1881	360	1072	217	677	1706	230	397	1861	47	6567
1882	398	1079	265	491	1230	68	318	2159	45	6108

The mortality from the local diseases was much higher than the average, the greatest increase being observed in apoplexy and paralysis, and in insanity. The deaths from pneumonia were 2932, or thirty-five less than in 1881.

The violent deaths were 898. The deaths from railroad accidents, 182, were more than ever before. The mortality from suicide, 162 deaths, remained very nearly stationary as compared with 1881. There were 12 deaths from homicide; 25 from the effects of heat; 26 from exposure; 60 from suffocation and strangulation; 6 from the effects of chloroform, and 2 from chloral; 5 from lightning; 107 persons were burned or scalded to death; 44 were fatally poisoned; 4 females died from starving, and 355 were drowned or lost at sea. A striking increase in the mortality from cancer and a decrease in pulmonary consumption are both probably in great measure due to the same cause, more accurate registration. The deaths from cancer were 987, of which 641, including 89 of cancer of the uterus, were of females. Of the 5865 deaths from pulmonary consumption more than one half were in persons between the ages of twenty and forty, representing for those ages 1302 deaths of males, and 1728 of females.

The report contains this year for the first time the statistics of divorces, which have increased from 1484 in the five years beginning with 1863 to 2650 in the five years ending in 1882. Of the 8610 divorces granted in the last twenty years 3148 were for adultery, 3660 for desertion, 696 for intoxication, 463 for extreme cruelty, 383 for cruel and abusive treatment, 190 for neglect to provide. The divorces on complaint of the wife were 67.9 per cent. of the total, and included all under the last-mentioned three heads, nine tenths of those for intoxication, two thirds of the divorces for desertion, and 1751 to 1897 for adultery.

PROVISION FOR THE CRIMINAL INSANE.

FROM time to time the JOURNAL has called the attention of its readers to this subject, and embraces the opportunity afforded by a hearing held last week before a joint special legislative committee, where it was considered for two days, of doing so again.

It is a matter of fact that there are now in Massachusetts lunatic hospitals no less than one hundred and fifty of the criminal insane, and according to Miss Barton, superintendent of the Sherborn Reformatory, there are twenty insane women in that institution. There is furthermore a very considerable number of insane convicts at the State Prison in Concord. The number of this class is becoming so large that on this account alone we can no longer hesitate to make an effort to adopt some form of special treatment for them.

Our laws provide for the transfer of all insane convicts to the lunatic hospitals, and the new hospital at Worcester was supposed to have wards especially adapted for their treatment. But what is actually the case? Although there are seventy of the criminal insane at the Worcester hospital, there are no special wards for their treatment (Dr. Parks stated at the hearing referred to above), all the wards being similar to those of other insane hospitals. And a large number of insane convicts remain in the prisons in spite of the laws allowing of their transfer. There must be some explanation of the latter state of affairs, as we have had evidence enough in times past that the prison authorities would gladly be relieved of their troublesome and dangerous insane, and we suppose it to be, at least in part, that the lunatic hospitals as at present organized are absolutely unable to manage the worst class of insane convicts.

It may be accepted then as conclusive, that we have a large number of the criminal insane in the institutions of this State. Those in the hospitals, we are told by all the superintendents, cannot be cared for in a manner suited to the other patients, the hospital organization, or themselves. Those in the State Prison and Reformatory can receive no adequate medical treatment and interfere with the discipline of the other prisoners.

What to do under all these circumstances was the question taken up by the legislative committee. On the first day of the hearing a plan favored by the Board of Health, Lunacy, and Charity was presented. This consisted in putting up a separate building on the prison grounds with a garden attached, to be under the charge, financially, of the warden, and medically, of the prison physician. This plan was opposed on the second day of the hearing by the chairman of the Board of Prison Commissioners and others.

Such an arrangement might involve less expense at the outset, but this advantage would be much more than offset by many disadvantages. As a department of the prison the asylum would of necessity be carried on on prison principles: for who could expect a warden to have any ideas as to the proper care of insane persons? And as the prison physician is usually un-

skilled in the treatment of mental diseases, and is a non-resident officer, dependent on his outside practice for the chief part of his support, he certainly would have neither the time nor training to enable him to properly organize an insane department. Furthermore, in our opinion, there is not room enough on the contracted prison grounds for a criminal lunatic asylum. The idea of the present day is not to shut the criminal insane up in a prison building within high walls, even if these walls inclose a garden. The very essence of the theory of separation is to remove them so far from any other class of criminals or lunatics that they will form a world by themselves, where no high walls will be necessary to hem them in, where they can live in an ordinarily built asylum, and benefit the State as well as their own health by labor on a good-sized farm.

The class of criminal insane is not by any means limited to insane male convicts. There are the female convicts, already alluded to, and furthermore, a large number of the unconvicted insane criminals, who have committed crimes wholly, or in part, as a result of insanity, and certainly should not be shut up within prison walls, and ostensibly classed as convicts, rather than lunatics. To pursue such a course would seem like returning to the old theory that insanity is an offense against society, rather than an unavoidable disease of a degenerated organ.

If we are to adopt a plan of separation, let it be the best one from the beginning. It will be sure to be cheaper in the end, as it will be for all time, instead of a temporary expedient. And let us above all things take no backward step in making a further classification of our unhappy and unfortunate fellow-beings, the insane. For it must not be forgotten that, in providing for them, we are performing a duty which is of interest to every citizen in the State who has had, or may have, a relative become insane.

MEDICAL NOTES.

—The number of medical examiners to be appointed by Governor-elect Robinson will be between fifty and sixty—not seventy-five as reported. The commission of about one third does not expire, but there may be a few resignations.

—The joint special committee appointed by the Legislature to consider during the recess certain matters pertaining to the charitable and reformatory institutions of the State is now giving hearings on the question of providing for the separate maintenance of the criminal insane.

—The Japanese anchor their temples against earthquake waves by attaching a heavy pendulum to the centre of the roof, the weight being only about a foot from the ground.

—It is reported that the young ladies of a somewhat famous female college of New England were alarmed at the universal and sudden prevalence of a diarrhoea of marked severity. Little moment, however, was attached to the incident by the authorities so long as the trouble was confined to the students, as they were sup-

posed to be suffering from the natural effects of over-indulgence in confectionery and the mild dissipations of female collegians. But the extension of the epidemic to those members of the Faculty who knew themselves to be without sin in that regard caused alarm. Investigation followed, and the fact was developed that the female practitioner to whom was intrusted the health of the institution had concluded, for some unknown reason, that the *primæ viæ* of the students needed clearing out, and had surreptitiously seasoned the apple sauce with rhubarb.

— At a meeting of the French Academy of Medicine, as reported in *Le Progrès Medical*, October 20th, a sketch was given by M. Marey of a case of congenital ectopia of the heart, in a female who had a bifid sternum and diaphragm with hernial protrusion. This anatomical peculiarity permitted the heart to be felt distinctly, just under the skin, and the aorta to be compressed through the fissure. The right ventricle was of course the most accessible to sight and touch. Except for a souffle of aortic stenosis the heart's action was normal. The appearance at first was as if the impulse were caused by the diastole of the ventricles, but it was soon shown to occur during systole. The graphic method of investigation showed the systole of the two ventricles to be synchronous, even when irregularities were produced in their rhythm. The investigations made upon this woman confirmed what has been observed in experiments by vivisection upon the higher mammalia. Thus obstacles introduced into the pulmonary or systemic circulation reacted in the same manner on the beat and modified its characteristics. The most important result from the observation of this case was to show that facts observed in the higher animals may be ascribed to the human subject as well.

— In Australia, where wild rabbits are a nuisance from their numbers and mischief, an ingenious veterinary surgeon has proposed to inoculate a number of these animals with tubercles, and to turn them loose with the hope of their infecting the others in their holes. But the plan is condemned by the popular press as inhuman, while medical minds are divided between the opposite views of the inadequacy of the means for destroying the rabbits at all, and of the danger of the tubercular infection going too far, or in other words acting like that other Australasian instrument, the boomerang, and returning upon its employers.

— Powdered cane sugar is described in the *Centralblatt für Chirurgie* as having been used with success by Professor Lücke as an antiseptic dressing for wounds. Here it was used in combination with naphthalin (equal parts), or in five parts of sugar to one of iodoform. It is applied under gauze in direct contact with the wound, and is left in place for eight to fourteen days before the sugar dissolves, the wound remaining clean and sweet. Another writer in the *Allgemeine medicinische Central-Zeitung* has used sugar alone as a dressing with equally good results, and considers it equal to iodoform as a dressing for small ulcers, though the sugar being aseptie rather than antiseptic, he prefers iodoform for chancres and for the fouler wounds and ulcers.

— It is said that among the recent improvements made at Guy's Hospital for the accommodation and convenience of students is the formation of a club and refreshment room which enables the industrious student to obtain a mid-day meal without going out to one of the dining and coffee houses in the neighborhood. The entrance fee is merely nominal, and the food cheaper and better served than that to be obtained elsewhere. Experience has shown that, so far from being a lounging room for the idle, those who frequent the club are industrious men, who desire to save the time lost in going outside the walls of the hospital. The club was opened last winter as an experiment, but its popularity has greatly increased, and a very large proportion of the students now avail themselves of its advantages.

— We have received the "Physician's Daily Pocket Record, comprising a visiting list, many useful memoranda, tables, etc.," arranged by Drs. S. W. Butler and D. G. Brinton, and published at the office of the Medical and Surgical Reporter. It is the eighteenth year of this very useful and well-arranged publication, and its career testifies of the usefulness which the profession has found in it.

Miscellany.

OBITUARY. DR. J. MARION SIMS.

DR. J. MARION SIMS, the brilliant and accomplished "father of gynæcology," died suddenly of disease of the heart at his residence in New York on the morning of November 13th, in the seventy-first year of his age. On the day before his death he was in excellent spirits, and remarked that he had not felt so well for a year. In the evening he went out to see a troublesome case with his son, Dr. Harry Marion Sims, and on his return wrote for some time on an autobiography upon which he was engaged, and about half of which he had already completed. He did not retire until after midnight, but slept uneasily, and about three A. M. woke up and commenced to write in bed, as was his custom when wakeful during the night. After writing a few lines, however, he lay down again and apparently went to sleep; but his wife, noticing that his breathing became heavy and unnatural, endeavored to rouse him. Failing in this, she became alarmed and called her son; but the latter had scarcely entered the room when his father gave a gasp and expired. An autopsy, made by Drs. Peabody and Welsh, in the presence of Drs. Loomis, Wyeth, and Wylie, showed that death was due to atheroma of the coronary artery. Since an attack of pneumonia three years ago, from which he barely escaped with his life, Dr. Sims had been accustomed to spend his winters in the south of Europe, and, at the time of his death, he expected to sail with his family from New York on the 17th of the month.

Dr. Sims was born in Lancaster District, South Carolina, January 25, 1813, and was graduated from the South Carolina College, at Columbia, in 1832. He began the study of medicine at Charleston, but attended lectures at the Jefferson Medical College, in Philadelphia, where he received the degree of M. D. in 1835. He commenced the practice of his profession

in Montgomery, Ala., and soon won a considerable reputation for skill in the treatment of the diseases of women, as well as in general surgery. In 1835 he published a series of articles in the *American Journal of the Medical Sciences* on Trismus Nascentium in which he developed an original theory of the disease; and about the same time began his experiments in regard to the treatment of vesico-vaginal fistula. In order to carry these on satisfactorily he established a private hospital for women in Montgomery, and after four years of diligent application demonstrated the entire curability of this hitherto hopeless affection by means of the silver wire suture. Much of the success of this, as well as of his other gynecological operations, was due to the vaginal speculum, which he invented, and which alone would have made his name distinguished throughout the world.

In 1849 Dr. Sims's health broke down, and for several years his condition was such as to interfere most seriously with all professional work. In 1853, however, he removed to New York, where his health soon became reestablished, and with a reputation secured by his previous achievements which placed him far above all competitors in his special department, he entered upon a career of brilliant success in a field in which there was the widest scope for his distinguished abilities. To his efforts alone was due the establishment of the Woman's Hospital, and this admirable institution, so completely identified with the triumphs of American gynecology, will undoubtedly constitute one of the most enduring monuments which will preserve his name to future generations. In the face of many and almost insuperable obstacles, and with a zeal and enthusiasm which could not be daunted, he carried this great object through to its completion. The foundation of such an institution became a cherished idea to him during the days of his sickness, and as early as 1854 he got up a public meeting at which the project was started by the appointment of a committee to organize the hospital, of which the late Peter Cooper and Drs. Valentine Mott, John W. Francis, and Edward Delafield were members. In May, 1854, the institution was opened in a temporary building, with Dr. Sims as surgeon-in-chief. In 1857 a charter was granted by the State, and in the following year \$50,000 was appropriated by the Legislature for the hospital, after which the site on which the present buildings stand was presented together with an appropriation of \$10,000 by the city. The selection of a plan was left mainly to Dr. Sims, and before adopting any he went abroad and made a thorough study of hospital construction and management in the principal cities of Europe. The war, however, interfered with the carrying on of the work, and it was not until 1866 that the first pavilion was completed and ready for the reception of patients. Although receiving material aid from the state and city, it has been mainly by private contributions that the institution has been sustained from the beginning, and it has been principally due to the indefatigable efforts of its illustrious founder that these have been secured. At a special meeting of the Board of Governors of the hospital, held November 15th, a minute in regard to Dr. Sims was adopted which reads, in part, as follows: "From the day of its organization until his departure for Europe, in 1861, he was its only surgeon, and practically developed then the improved methods of operating which he had originated. . . . During thirty years of his active life he devoted his

talent, time, and influence to place this institution upon a successful basis." During his absence in Europe his position at the hospital was filled by Dr. Thomas Addison Emmet, and when, after his return, the Board of Surgeons was reorganized to consist of four members, he was appointed to one of the positions, the other three surgeons being Drs. Thomas, Peaslee, and Emmet. Several years ago the Board of Governors of the hospital made some rules involving certain restrictions in regard to operations, and believing that this was an unwarranted infringement upon the rights of the surgeons, Dr. Sims, with the impulsiveness which always characterized his actions, promptly tendered his resignation; since which time he has not been actively connected with the institution, although continuing a member of the committee of surgeons.

When he went to Europe, where he resided for the most part from 1862 to 1868, Dr. Sims met with a very flattering reception from the most distinguished members of the profession, and quickly added new laurels to his fame by his brilliant operations performed in the presence of the principal surgeons of England, France, and Belgium. He was made a Knight of the Legion of Honor by Napoleon III., and was also decorated by the Belgian, Spanish, Portuguese, and Italian governments, while he was elected Corresponding Fellow of various learned societies in London, Edinburgh, Brussels, Berlin, Christiana, and other foreign capitals. Being again in Europe in 1870, he was induced to take charge of the Anglo-American Ambulance Corps, and as its surgeon-in-chief won imperishable honors in the field, particularly at Sedan, where this was the first ambulance corps to arrive. In this work he was ably seconded by the distinguished English surgeon, Sir William MacCormac, who less than a month ago was Dr. Sims's guest at a brilliant entertainment given in his honor at the house of the latter in New York.

Among the principal of his literary works may be mentioned the following: Trismus Nascentium, Silver Sutures in Surgery, Clinical Notes on Uterine Surgery, Intra-uterine Fibroid Tumors, The Microscope in the Sterile Condition, A Treatise on Ovariectomy, and A History of the Discovery of Anæsthesia. The last-named monograph, in which he sought to prove that the use of ether was first discovered by Dr. Long, of South Carolina, involved him in a protracted discussion with various members of the profession, but he defended the claims of his friend with all his accustomed zeal and pertinacity. One of the honors of his life, of which Dr. Sims was most justly proud, was his selection as President of the American Medical Association in 1876, and the centennial address before the Association was delivered by him in Philadelphia on the 6th of June of that year, before a memorable audience. His kindness of heart, his uprightness of character, his geniality, his boundless generosity, and his personal magnetism, made him universally beloved and esteemed, and of scarcely any other American can it be said with equal truth, that he created a new era in medicine.

In December, 1836, Dr. Sims married the accomplished daughter of Dr. Bartlett Jones, of Lancaster, S. C., and his wife, two sons, and five daughters survive him. At the funeral services, which were held November 16th at the Madison Square Presbyterian Church, and which were attended by a vast concourse, a memorial sermon was preached by the Rev. Dr. Parkhurst, pastor of the church.

OBITUARY. DR. GEORGE J. ARNOLD.

GEORGE JEROME ARNOLD, eldest son of Hon. David Arnold, was born in Londonderry, Vt., May 28, 1835. He entered the Harvard Medical School in 1858, graduating in the spring of 1861, and commencing practice in Roxbury, Mass., a few months afterwards. In August, 1862, he was appointed assistant surgeon of the Twelfth Wisconsin Light Artillery with which he served seven months at the seat of war. Returning to Roxbury he acted for several years as physician to the Roxbury Dispensary and Almshouse, and also as surgeon to the Roxbury City Guards. About 1870 he became visiting physician to the Boston City Hospital, which position he held till 1881 when compelled to resign on account of ill health. In September, 1882, he relinquished practice altogether and removed to Wayland, hoping to restore his exhausted energies by a season of complete rest. He died at Old Orchard, Me., October 3, 1883, from the accidental discharge of a pistol which he was engaged in cleaning. By the explosion a wooden ramrod several inches in length was blown nearly through the abdomen, entering on the right side, and lodging beneath the skin near the crest of the left ilium, where it was cut down upon and removed. He died, how-

ever, on the second day following, from peritonitis. At the autopsy, besides the effects of the wound, the gall-bladder was found completely filled by a calculus the size of an English walnut, which had been the source of intolerable suffering during life.

Dr. Arnold was an indefatigable worker, and had at one time a large and lucrative practice. He was for a number of years treasurer of the Norfolk District Medical Society, and represented it repeatedly in the council. He was married May 28, 1861, to Miss Anna E. Bullard, of Wayland, and his domestic relations were known to have been exceptionally happy. His wife, with five children, the eldest now a student in Harvard College, all survive him.

OBITUARY. DR. MARSHALL S. MEAD.

DR. MARSHALL S. MEAD, for many years one of the most prominent physicians in Franklin County, died recently at his home in Northfield, Mass. He was born in Chesterfield, N. H., June 4, 1802. He practiced medicine in Northfield fully half a century, and was widely known and popular. He was a member of the Massachusetts Medical Society.

Deaths reported 2302 (no report from New Orleans): under five years of age, 773: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 482, consumption 377, lung diseases 253, diphtheria and croup 183, typhoid fever 87, scarlet fever 62, malarial fevers 25, measles 17, puerperal fever 10, cerebro-spinal meningitis nine, whooping-cough nine, erysipelas seven, small-pox two, typhus fever one. From *scarlet fever*, Philadelphia 13, New York, Chicago, and Boston eight each, Brooklyn six, Baltimore five, St. Louis and Buffalo three each, Pittsburg and Providence two each, Milwaukee, Lowell, Worcester, and Gloucester one each. From *malarial fevers*, New York eight, St. Louis and Baltimore five each, Brooklyn four, Chicago two, New Haven one. From *measles*, District of Columbia eight, New York three, Baltimore two, Philadelphia, Brooklyn, Boston, and Providence one each. From *puerperal fever* St. Louis three, Philadelphia, Brooklyn, Chicago, Boston, New Haven, Nashville, and Cambridge one each. From *cerebro-spinal meningitis*, New York three, Springfield two, Philadelphia, Chicago, St. Louis, and Cincinnati one each. From *whooping-cough*, New York three, Brooklyn and District of Columbia two each, Chicago and Pittsburg one each. From *erysipelas*, Philadelphia two, Brooklyn, Chicago, Boston, St. Louis, and Baltimore, one each. From *small-pox*, Philadelphia two. From *typhus fever*, New York one.

Six cases of small-pox were reported in St. Louis; scarlet fever

35, diphtheria 33, typhoid fever 17, and measles six in Boston; diphtheria three and scarlet fever three in Milwaukee.

In the 32 cities and towns of Massachusetts, with an estimated population of 1,040,987 (estimated population of the State 1,922,530), the total death-rate for the week was 17.52 against 19.08 and 18.69 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending October 27th, the death-rate was 20.2. Deaths reported 3329: acute diseases of the respiratory organs (London) 291, scarlet fever 130, diarrhoea 114, fever 62, measles 58, whooping-cough 51, diphtheria 35, small-pox (London and Birmingham two each, Sunderland one) five. The death-rates ranged from 12.3 at Portsmouth to 28.8 at Salford; Leicester 14.5; Birmingham 15.9; Sheffield 18.9; London 19.1; Nottingham 19.4; Blackburn 21.6; Birkenhead 21.8; Liverpool 25.1; Leeds 26.3; Manchester 28.1. In Edinburgh 19.7; Glasgow 26.1; Dublin 24.9.

For the week ending October 27th, in the Swiss towns, there were 23 deaths from consumption, lung diseases 13, diarrhoeal diseases 18, diphtheria and croup three, whooping-cough two, typhoid fever two, measles one. The death-rates were, at Geneva 9.2; Zurich 4; Basle 15.1; Berne 20.3.

The meteorological record for the week ending November 10th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps:—

Date.		Barometer.	Thermometer.				Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THREE WEEKS ENDING NOVEMBER 17, 1883.

EDGAR, J. M., assistant surgeon, from the Receiving Ship St. Louis, at League Island, Penn., to the Receiving Ship Wabash, at Boston, Mass.

AUSTIN, A. A., past assistant surgeon, to the Receiving Ship St. Louis, at League Island, Penn.

HALL, C. H. H., passed assistant surgeon. Ordered to the Naval Academy, Annapolis, Md.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM NOVEMBER 2, 1883, TO NOVEMBER 16, 1883.

BACHE, DALLAS, major and surgeon. Ordered to report in person to the commanding general, Department of the East, for assignment to duty. Paragraph 10, S. O. 259, A. G. O., November 12, 1883.

GARDINER, J. DE B. W., captain and assistant surgeon. Relieved from duty at Fort Huachuca, and assigned to duty as post surgeon at Fort Bowie, A. T. Paragraph 1, S. O. 104, Department of Arizona, November 8, 1883.

EGAN, PETER R., first lieutenant and assistant surgeon.

Upon being relieved from duty at Fort Bowie, A. T., to proceed without delay to Fort Huachuca, and report to the commanding officer at that post for duty. Paragraph 1, S. O. 104, Department of Arizona, November 8, 1883.

PRICE, CURTIS E., captain and assistant surgeon. Assigned to duty at Fort Custer, M. T. Paragraph 1, S. O. 187, Department of Dakota, October 25, 1883.

WILSON, GEORGE F., first lieutenant and assistant surgeon. Assigned to temporary duty at Fort Townsend, W. T. Paragraph 2, S. O. 149, Department of the Columbia, October 29, 1883.

APPOINTMENTS. HARVARD UNIVERSITY.—Dr. S. H. Durgin has been appointed Instructor in Hygiene, and Dr. Charles H. Williams Instructor in Ophthalmology.

BOOKS AND PAMPHLETS RECEIVED.—Students' Manual of the Diseases of the Nose and Throat. A Digest, descriptive of the more commonly seen Diseases of the Upper Air-tract, with the Methods of Treatment, by J. M. W. Kitchen, M. D., Assistant Surgeon to the Metropolitan Throat Hospital, etc. New York: G. P. Putnam's Sons. 1883.

Annual Report of the Supervising Surgeon-General of the Marine Hospital Service of the United States. For the Fiscal Year 1883. Washington: Government Printing Office, Treasury Department.

ABDOMINAL TUMORS IN CHILDREN.
SIX CASES.

BY EDWARD N. WHITTIER, M. D.,

Physician to Out-Patients Massachusetts General Hospital, Instructor in
Theory and Practice of Medicine Harvard University.

THE following series of cases involving the wide subject of abdominal tumors in children is presented simply as the history of the cases and their varying phases while under observation. The group may serve to illustrate the extreme difficulty of reaching conclusions sufficiently definite to be of great value while dealing with so floating a material as that composing an out-patient service, and to satisfy the reader, as the preparation of this paper has already satisfied your reporter, that with all of the best known methods freely placed at our disposal the diagnosis of such growths and accumulations must necessarily be involved in great obscurity.

CASE I. FÆCAL TUMOR OF UNKNOWN DURATION
OCCUPYING THE DESCENDING COLON.

From the mother, a thin, feeble woman, of highly nervous temperament, the following history was obtained:—

The child, a girl eight and a half years old, had never been particularly strong, was always delicate, had escaped the ordinary diseases of children excepting measles, but required great care and watchfulness, for she acted at times as if she was hysterical.

Since the child was a year and a half old there had been repeated attacks of "constipation." When first observed the mother said she would go a week if left to "nature," and that this condition had gradually grown into longer periods of constipation up to the present time. Yet it was only since second dentition was fully established that the complaint had assumed such formidable proportions, so that early last year she was three weeks without a defecation; last June she had been five weeks; and at Christmas was terminated six weeks' constipation. Closer questioning, however, developed the fact that since Christmas there had been the frequent escape of small quantities of feces, and generally involuntary, obliging the child to wear napkins. The mother's anxiety lest her child should again become constipated led her to the hospital.

The girl, poorly nourished, not very intelligent, and excessively nervous, did not afford a satisfactory examination, her mother fearing that the child would have a fit, which she said an examination by the rectum always produced,—that even the use of a rectal injection often threw her into convulsions. Hence friction was advised, tincture nux vomica three times a day, and Hunyadi each morning, and relief was secured.

At the end of eight weeks the mother reappeared with the story of three weeks' constipation.

Examination of abdomen revealed the presence of a tumor occupying the left hypochondrium, lumbar, and inguinal regions, and extending nearly to umbilicus. This tumor proved to be a soft, non-elastic, non-fluctuating, but easily moulded mass, yielding to pressure, but not disappearing, and incommoding the child only by its increasing weight.

Because no other examination was allowed the mother was advised to enter the hospital for further advice

and treatment, but as she was not willing to comply with the hospital regulations she disappeared, and all traces of her were lost.

The accompanying diagram represents the size and position of the tumor at the time of my last examination.

FIG. 1.

The difficulty of reaching any positive conclusion as to the cause of this fecal accumulation is sufficiently evident. During even my superficial examination, required to map out the boundaries of the tumor, the child grew very hysterical, and was convulsed. I thought the mother would have a fit also. It was clear that nothing could be well done without ether, and that we could not obtain permission to use. Hence the diagnosis involved the following undetermined questions:—

Congenital malformation of large intestine.

Constriction of lower part of large intestine by a neoplasm.

Constriction by adhesions or bands of false membrane.

Paralysis of the muscular walls of the large intestine due to habitual constipation, and hysterical paresis.

Prolonged constipation has, as one of its most definite results, impairment of the peristaltic action of the large intestine; occasionally, and not infrequently, there is found hyper-extension, notably of the descending colon; at times a further obstacle to the passage of feces is due to the fact that the intestine lying below the paralyzed portion becomes contracted, the contraction of inanition, and thereby increases the resistance offered to the passage of the accumulated fecal mass. I therefore offer this as the most reasonable solution of the problem presented by this case.

The termination of the most prolonged period of constipation in this child was signalized by the frequent escape of small quantities of semi-liquid feces; shorter periods had terminated by the sudden evacuation of large quantities of fecal matter.

CASE II. PROBABLE SARCOMA OF RIGHT KIDNEY.

The patient, a girl of healthy parentage, was noticed by her mother, some seven months previous to my observation, to make complaint of pain and tenderness in her right side, and about the same time the mother discovered a small, hard lump in the right lumbar region. Various opinions were sought and received, but at last the child was brought to the hospital, and was turned over to me by Dr. Curtis.

The mother assigned the child's complaint to an injury received while playing with her other children on a swinging gate early in the summer; other than this no cause remote or proximate could be ascertained, and the rapid growth of the tumor in the month of November led her to the hospital.

The child was a thin, pale, distressed-looking girl, extremely weak, with no variation from the normal condition of the thoracic organs save some upward displacement. The abdominal walls, thin and wasted, were distended in the right lumbar region notably by a dense mass, quite regular in general outline, but

FIG. 2.

nodular over the anterior surface nearest the umbilicus; this mass was firm and resisting, easily displaced upwards, forwards, and inwards by the hand placed in the region of the right kidney. The circumference of the abdomen was then eighteen inches, and the tumor extended to the umbilicus, occupying the right lumbar region and part of the right inguinal and right hypochondrium of same side. Two weeks later the tumor had pushed across the umbilical region, and in a little more than a month from the time of the first observation and record the mass filled nearly the whole abdominal cavity, the child emaciating very rapidly, yet gaining six inches in abdominal circumference.

The child died of exhaustion. No autopsy was granted.

CASE III. CYSTIC DEGENERATION OF RIGHT KIDNEY.

FIG. 3.

By Dr. S. Cabot's permission I am able to present the following case from the records of the hospital:—

The patient, a sickly-looking child, was very much

emaciated. The parents state that four months previous to entrance, and when about a year old, it was noticed to have enlargement of abdomen; this increased very rapidly; at the end of the fourth month it had extended across the median line about two inches. Some time later than this I first saw it. The tumor, irregular in outline and in surface, occupied nearly the whole abdominal cavity; was dull, dense, and resisting, and at points giving a very indistinct sense of fluctuation. Intestinal resonance even in modified form could be made out only in the left hypochondrium and left inguinal regions.

The accompanying diagram represents the size and position of the tumor.

Early in December Dr. Cabot aspirated the tumor and secured a small quantity (half ounce) of bloody fluid. This seemed to be contained in several small cysts, and was obtained by pushing the needle in various directions.

Dr. Fitz reported on the fluid as follows: "I found nothing with the microscope to indicate the source of the fluid sent me. Red blood corpuscles, fat drops; rare cholesterine crystals and fatty degenerated cells were found; the latter were either flat or round, and might have come from the peritoneal wall as well as elsewhere."

When nineteen months old the child died, and this note of the autopsy was sent to the hospital:—

"An immense collection of cysts originating in right kidney; in fact that organ was converted into a cystic tumor; the whole weighing seven and three fourths pounds. All the other abdominal organs healthy. Death hastened by a slight attack of bronchitis. The tumor did not begin to tell upon the health of the child until about six weeks before death. The cysts contained nothing but clear serum."

The physician in charge at the time of the child's death sent a report of the case to the JOURNAL for publication.

CASE IV. CYST OCCUPYING THE RIGHT HALF OF THE ABDOMINAL CAVITY. CONGENITAL; PROBABLY HYDRONEPHROSIS OF RIGHT KIDNEY.

E. S., female infant, was brought to the hospital when five and a half months old, with the following history: At birth, the breech presenting, the child was extracted, but without much difficulty, and was noticed to have a misshapen belly. The attending physician said that the muscles on the left side of the neck were undeveloped, in consequence of which the head was turned for some time to one side, and the left foot was in position of valgus. There was also a malformation of the hard palate.

At the time of my first observation, the mother, an intelligent young woman, complained for her child chiefly on account of the great and increasing swelling of the belly, and the child's consequent distress, which required the constant use of opiates. The child was carefully examined, with the following result: The palatal portion of the superior maxilla had united at a very acute angle, and on either side near the alveolar processes a strongly marked ridge or buttress had been thrown out, nearly masking the view of the hard palate.

The left foot was but little distorted, but the abdominal walls were greatly distended by a tumor occupying the right half of the abdominal cavity, displacing the liver upwards and the small intestine to the left side.

The tumor was a uniformly rounded body, with a slight constriction in lower and anterior boundary, giving a very indistinct fluctuation, and movable upwards and inwards on pressure exerted from behind.

The accompanying diagram represents as nearly as may be the size and position of the tumor:—

FIG. 4.

The child was sent to the hospital and entered the service of Dr. Minot, who kindly assented to an exploratory puncture with hypodermic needle. This gave a clear neutral fluid containing albumen.

On the following day Dr. Minot aspirated the cyst, removing thirty-eight fluid ounces, to the entire relief of the patient. Dr. Hill's very complete analysis of the fluid is as follows:—

Slightly turbid when received.

Reaction neutral.

Specific gravity, 1000.

Sediment vibrios, few blood corpuscles and round cells:—

Total solid residue	1.165 per cent.
Water	98.835 per cent.

100.000 per cent.

Of the 1.165 per cent. solid residue there was —

Of organic and volatile residue	0.798 per cent.
Inorganic residue	0.367 per cent.

1.165 per cent.

Of the 0.798 per cent. organic and volatile residue there was —

Fat	0.028 per cent.
Urea	0.073 per cent.
Albumen	0.323 per cent.

0.424 per cent.

The only variety of albumen present was serum albumen. No cholesterine present.

The remainder of the organic and volatile residue was probably chiefly derived from the decomposition of inorganic substances upon ignition.

Nine weeks later Dr. Ellis aspirated, obtaining twenty-six ounces of similar fluid, and on the 10th inst., an interval of eleven weeks, I drew off fourteen ounces.

The report of the analysis of the fluid, while more complete than any to which I have been able to obtain access, does not throw much additional light on its source. The fluids of cystic kidneys are quite likely, however, to be without distinguishing characteristics. But the history of the growth, its position, its contents, and the attempt at malformations elsewhere are to be regarded as important factors, enabling us to reach a conclusion that the cyst had its origin in the kidney, and was dependent upon a malformation in the course of the ureter or at its point of union with the bladder.

An additional element of much interest was described by the mother at the time of her last visit. That at times after very considerable increase in the size of the tumor, and great distress on the part of her child, there would be a noticeable diminution in size, and relief to the child, corresponding to that seen after aspirating.

This condition suggests very forcibly that the obstruction is essentially valvular, and that the case is of that class in which the most satisfactory explanation is that of a mechanical obstruction yielding to an increasing pressure.

CASE V. CYST OF UNKNOWN ORIGIN OCCUPYING THE GREATER PART OF THE ABDOMINAL CAVITY. ONE AND A HALF YEARS' DURATION.

FIG. 5.

A healthy boy, two and a half years of age, had been perfectly well save an attack of "croup" a year or more ago, and that during last summer he had diarrhoea, and was very weak for a long time afterwards.

When he was about a year old he was noticed to have some abdominal enlargement, and this had been progressive up to the date of his coming to the hospital, where I first saw him and advised his admission.

There had been at no time, so far as could be learned from his mother, a rather intelligent woman, anything like an acute inflammatory disturbance of a kind more marked than the diarrhoea of last summer. No symptoms referable to the abdomen other than those of size and weight. Never jaundice nor evidence of the "dropsies" of any other part of the body. No cough; no dyspnoea; no swelling of feet or hands. The urine on examination proved to be normal; there were no cardiac and no pulmonary complications. In every respect save that of great abdominal enlargement the child was well formed and well nourished.

The patient entered the Massachusetts General Hospital and the service of Dr. Minot, by whose permission I am able to give the accompanying report of the case while under observation there:—

"A child of healthy aspect, with an abdomen greatly distended and fusiform, fluctuating and dull on percussion everywhere. Anterior wall completely covered with a net-work of distended veins. No swelling of hands or feet. Some puffiness of eyelids."

January 28th Dr. Minot tapped and drew off sixty-two fluid ounces of a dark brown color, loaded with cholesterine. The following is Dr. Hill's report of the character of the fluid:—

Color, brown.
Specific gravity 1016.

Reaction slightly alkaline.	
Solids	4.28 per cent.
Water	95.72 per cent.
	100.00 per cent.
Serum albumen	2.95 per cent.
Inorganic salts790 per cent.
Urea052 per cent.
Blood pigment fat and dry residue of sediment	1.486 per cent.
	4.280 per cent.
Sediment—Cholesterine.	
Blood globules.	
Granular corpuscles.	

After the tapping there was found under the free margin of the liver a round, apparently solid mass, projecting downwards to within a short distance of the umbilicus.

Some nine weeks after the tapping the child was brought to my office by the mother, who expressed the fear that he was again filling up. An examination revealed the fact that the abdominal enlargement was again increasing, but in a way very different from that expected; it was from above downwards; a soft fluctuating tumor displacing the liver and chest walls upwards and outwards, and having its lower boundary in the central line nearly or quite opposite the umbilicus.

Under the margin of the ribs in the hepatic region could still be felt the solid resisting mass found after the tapping. No other variations were observed. I have endeavored in my diagram to figure the position of the tumors on the different dates, and have marked them, as shown by my examinations.

I regret to state that I have been utterly unable to find any explanation of this condition of things which seems to me to offer a satisfactory solution of the problem, and it is only by reason of the second examination that I have had any right to reach the conclusion that we had to deal in this case with an encysted fluid, limited by walls less in extent than the peritoneum.

My earlier impressions were that the illness of last summer was complicated with peritonitis, and that the fluid was not very different from that which is occasionally seen in the rare form described as chronic diffuse peritonitis.

CASE VI. ABDOMINAL CYST; CENTRAL; UNILOCULAR; OF UNKNOWN DURATION.

L. H., four years old, was noticed by his mother, two years previous to my first examination, to have some abdominal enlargement. But little importance was at-

tached to this at the time, and but little notice was taken of it until the mother was obliged by his complaints to lengthen his waistbands, and a more careful examination showed a marked fullness in the lower part of the bowels; this increasing, a physician was consulted, and the "dropsy" was treated in the usual manner, without the sometimes so-called good results. The boy grew larger, steadily increasing in size from below upwards, and without any symptom of local or constitutional disturbance other than that growing out of the increasing weight. There was no swelling of any other part of the body. No cough; no dyspnoea; in fact, no disturbance save that directly traceable to the increasing weight and distention referable to the abdominal enlargement, and by reason of this the child was brought to the hospital for treatment.

In every respect save that of a greatly distended abdomen the child was in excellent condition. The thoracic organs were displaced upwards, but uniformly. Hepatic and stomacal regions were similarly changed in position. No marked enlargement of abdominal veins. The abdomen was distended fully and uniformly, giving very indistinctly the wave movement on palpation; this was thought to be due to the extreme degree of tension of the abdominal walls until by percussion it was determined that as change of position gave no change in note, and that as intestinal resonance, first detected in the right and left hypochondria, grew more marked until in the epigastric region it was fully developed, where deep pressure gave the upper boundaries of a round, smooth body, there were the limiting walls of what seemed to be an extremely tense cyst. This was the conclusion also reached after consultation with Dr. Ellis, and aspiration was determined upon, and a few days later I drew off eighty-eight ounces of a dark-brown fluid, crowded with cholesterine, of which the following analysis, carefully made by Mr. Peckham, Professor Wood's assistant at the time, deserves better record than I can give it:—

Color, dark brown.

Specific gravity, 1021.

Reaction, neutral.

Sediment, large, and consisting of cholesterine and old partially decomposed blood corpuscles. The dark-brown coloring matter was due to haematin.

No sugar.

Ether extractive matter consisting of

fat and cholesterine	1.71-125 per cent.
The amount of dry albumen	5.64 per cent.
Amount of solids after ignition	1.36 per cent.
The amount of urea00153 per cent.

The solids after ignition consisted of sodium, potassium, and magnesium and calcium combined, combined with hydrochloric, sulphuric, and phosphoric acid.

No reaction followed the operation. Succeeding examination only revealed in the hypogastric region the collapsing walls of the cyst. Six months after the operation all trace even of this was entirely lost, and when last heard from, a couple of weeks ago, the child was pronounced by his mother to be "as well as any one's boy."

FIG. 6.

— The *Lancet* completed its sixtieth year on October 5th. The first article in its first issue was a lecture by Sir Astley Cooper, delivered at St. Thomas's Hospital.

A NEGLECTED FIELD OF MEDICAL SUPERVISION.¹

BY C. B. SHUTE, M. D., MALDEN.

AFTER hearing the quotations from the eminent authorities which we have given, and comparing their conclusions with the results of our every-day experience, we feel that we can safely affirm that dipsomania should be considered a form of insanity, and therefore in common with all other diseases it should claim the attention of the physician in order that the condition of the victims of this fearful evil may if possible be ameliorated.

We therefore ask the practical question: What can the medical profession do for these unfortunates in the way of treatment? The obstacle here presents itself that the patient is unwilling or unable to take the first step in the treatment of disease, namely, that of removing the cause of the disease. As we have remarked before, rarely will either the patient or his family ask for our advice. Whatever then we have to offer him must be forced upon him. The employment of drugs is well nigh useless. No known drug can successfully counteract or destroy the slavish habit. We have but one remedy at our disposal, but that fortunately promises to be a most efficient one, namely, isolation in some appropriate asylum for a prolonged period. Forcibly removed from an evil which these patients are of themselves unable to avoid, we may hope to secure some grand results. Minds, which were directed only in one channel towards the gratification of a debasing appetite, may, when the impossibility of satisfying that appetite is seen, confidently be expected to begin to develop in some different direction under a proper course of discipline.

In some instances dipsomaniacs have been sent to insane asylums, where they may enjoy the rest and effect the abstinence that may be required. But it is obvious that unless the means of classification of the inmates are greater than is usually the case, the ordinary insane asylum is not an appropriate place of confinement for the class of persons under consideration. The most favorable plan in dealing with the evil in question, and the one which I wish to advocate in this paper, is that of establishments expressly designed for the reception and treatment of inebriates. This plan for the treatment and cure of dipsomania is not by any means a new one. Twenty-five years ago it was earnestly discussed and ably advocated in the Medico-Chirurgical Society of Edinburgh by such men as Skae, Christison, and Peddie. Dr. Peddie read a paper before the Society on The Necessity for Some Legalized Arrangements for the Treatment of Dipsomania. He contended that, while it was impossible to come to any strict definitions on the subject, all persons laboring under not merely mental aberration but moral perversions which interfered with public safety and well-being, or under that form of cerebral disease known as dipsomania, who, having not that self-control which virtually made them responsible agents, were yet amenable to law if they fell into crime, should, for the best interest of society and their own, be subjected to restraint in an asylum and be detained there not merely till the paroxysm of excitement should have passed away, but for such a time as gave hope of a permanent restoration to sound mind and social habits, and to a state of capability to discharge social duties

as hospitals for the insane, namely, that of retaining and exercise civil rights. He recommended: (1.) Separate institutions, distinct from ordinary lunatic asylums, under the management of public boards. (2.) These boards should be composed of a magistrate, a justice of the peace, a clergyman, and a physician. (3.) Appeals, in cases of complaint in treatment or undue detention, should be made to the Home Secretary, or to a Lunacy Commission. (4.) Applications for treatment might be voluntarily made by dipsomaniacs; for compulsory restraint, they should be made by friends or relatives, or, in exaggerated cases, by the sheriff. (5.) That all applications for compulsory restraint should be made through the sheriff, setting forth, among other things, that for so long a period the dipsomaniac had suffered from the disease, that all ordinary means of cure had proved unavailing, and that all power of self-control was gone. (6.) That the principal statements of the petitions should be attested by two witnesses, one of whom should be the medical attendant, and the other a physician to be appointed by the sheriff. He expressed the belief that such a scheme might be carried out at very little expense to the public — for the institution might be made nearly self-supporting, and that any extra expense incurred would be more than saved in lessening the number of those who, for want of timely interposition, ended their days in poor-houses, prisons, or in lunatic asylums, as incurably insane.

In 1872 Dr. Mitchell, Commissioner of Lunacy for Scotland, urged the establishment of asylums for dipsomaniacs before the Committee of the House of Commons. He says that his experience in Scotland is far from encouraging, but the experiment has never fairly been made, and, in his opinion, if it were tried under special legislation, we might reasonably expect good results. There should be tentative legislation, such as would give us the opportunity to acquire the experience we need. At the same time there are certain safeguards that would be required. The legislation might lead to abuse, and this abuse it would be necessary to guard against. It should not be left entirely to medical men to settle this, as it is not entirely a medical matter. There should be something of the nature of an inquest and, so far as Scotland is concerned, he thinks the order of a sheriff should always be necessary to authorize the detention of a drunkard, and that the duration of that detention should be fixed in the order. There should always be a way of prolonging the detention in certain cases, and likewise a channel of appeal for cases of undue detention. He advocates that persons should be received voluntarily into such institutions, but should not be allowed to leave sooner than a fixed time; also that the asylums should be of two kinds, one for paying, and the other for non-paying, patients; also that some might be established for those who entered voluntarily, and others for those who entered involuntarily. These views of Dr. Mitchell were ably seconded by Dr. Clouston, the editor of the *Journal of Mental Science*.

In the *Scotsman* for January, 1877, a sort of permissive legislation is urged, whereby such institutions should be placed under state supervision and control, Parliament being asked to do nothing more than sanction the compulsory detention of persons found after legal inquest to be in a condition requiring treatment in an inebriate asylum.

These institutions labor under the same difficulty

¹ Concluded from page 487.

ing their cases sufficiently long to make a permanent impression. Even the most of those who consent to become patients have no idea of prolonging their seclusion after the immediate effects of indulgence have disappeared. They say that they feel perfectly well, have not the slightest desire for drink, and, therefore, that further seclusion would be not only unnecessary but prejudicial to their mental and bodily health. Thus beguiled by a morbid confidence in themselves, they determine to reassume their liberty, in spite of entreaty and argument, and the institution has no power to prevent it, unless authorized so to do by the laws. But, as Dr. Peddie well remarks, it is the name of liberty, and not the thing, which presents difficulty in proper legislation on the subject. He considers that it is the duty of a good government to interfere in such cases, when all self-control is gone, and so much personal and relative interest is at stake. Already the laws do much to guard against the squandering of property by such persons. Why should they not do something for the personal welfare of the individual himself?

In England some progress has already been made in this direction. The Habitual Drunkards' Act, which came into force January 1, 1880, was enacted to enable habitual drunkards to surrender their liberty for a period not exceeding twelve months, that they might secure for themselves the conditions most favorable to a cure. But this act is very defective. As a man has to confess himself an habitual drunkard before two magistrates, it proves a barrier to applicants for admission to a "Retreat," as it is styled. However, the medical profession in England are doing their best, under the imperfect law, and the "Dalrymple Home for Inebriates Association" has been registered, this body including in its membership such men as Drs. Duckworth, Alfred Carpenter, and Norman Kerr.

In America, with the exception of a few States, progress in the treatment of dipsomania has not been as satisfactory even as in Great Britain. To Dr. Benjamin Rush, of Philadelphia, belongs the honor of first elaborating the subject and outlining what has been accepted nearly a century later. In 1790 he described the disease of inebriety, and urged that it should be treated in a hospital devoted to this purpose. Fifty years later in our own State Dr. Woodward, of Worcester, maintained that inebriety was a disease and curable as other diseases in asylums. He remarks, "If there are 30,000 drunkards in this country, and one tenth part are susceptible of cure, it will afford adequate motive to commence immediately the important work of establishing asylums for the inebriate. Doubtless one half may be cured and the habit be wholly removed, if proper means are persisted in for a suitable length of time."

More recently Dr. Earle, of our own State Society, states that his experience in the treatment of dipsomania "convinces him that there is little hope of recovery so long as there is no legal authority for the detention of its subjects for a much longer period than they will voluntarily remain under restraint."

Dr. Austin Flint, Sr., President of the American Medical Association, in speaking of the treatment of this disease, says: "The successful management is rarely practicable except by means of institutions in which the patient is under the same restrictions as in insane asylums."

Dr. N. S. Davis, of Chicago, asserts as "the conclusion of a long life of observation and study concerning this subject that nothing less than a protracted isolation will afford any fair prospect of recovery in dipsomania. For chronic or persistent inebriates he advocates the establishment of asylums, which should be maintained under State or municipal authority. Admission to these should be through legal process, with legal authority to detain for such a length of time as will insure thorough renovation and recovery, this term being not less than one nor more than five years, unless sooner discharged for good conduct and full recovery by the superintendent in charge of the institution. Such a system would place the legal relations and personal liberty of the confirmed inebriate on the same level with the insane, with institutions specially adapted to effect his reformation, and at the same time protect his friends, family, and the whole community from the depredations and crimes so constantly being committed by the class to which he belongs."

Several medical societies have passed resolutions urging that institutions of this character be established, and in a few States, notably in New York, Connecticut, Maryland, Minnesota, and California, laws have already been enacted, by which the inebriate can be committed and legally detained. New York and Maryland have State institutions, but in most cases private corporations have charge of asylums of this nature, and the treatment is not always in the hands of those approved by the medical profession.

In 1876 the mayor of Boston appointed a committee of three, consisting of Rev. Dr. A. A. Miner, Dr. Geo. C. Shattuck, and Dr. John E. Tyler, to examine and report on the treatment of drunkenness in the city institutions, and to suggest some measures looking to the reform of this class. In their report the committee condemn the method of dealing with drunkards which is common in all our large cities, by which men are fined in some small amount or sent to a work-house or penitentiary for some short period, commonly thirty days. If the fine is paid the burden falls upon the family or friends of the drunkard, who are innocent of all fault, and are punished by the mere fact of his drunkenness. If he is sent to prison, the term of his confinement is long enough for him to get sober, but not long enough for him to acquire habits of sobriety. The consequence is that a restoration to liberty is followed by a new spree and another commitment. The Commissioners suggest that the city of Boston should convert the institution at Deer Island into a sort of reformatory, where all kinds of agriculture and mechanical labor can be carried on. Thither drunkards should be sent for terms long enough to enable their constitutions to recover thoroughly from the effects of alcohol, and to give them an opportunity to acquire habits of industry. In some cases a year would be long enough for this purpose; in others three years might be required. They believe that there would be enough of punishment involved in the reformatory process to make it thoroughly salutary.

In Massachusetts there are no State inebriate institutions, there are no laws whatever encouraging or governing the proper treatment of this unfortunate class. We have had laws restricting and laws licensing the sale of alcoholic liquors, with modifications almost without number, and all with indifferent success in their execution, so that now the community seems to

be in a condition of honest doubt as to which law is the better, or whether any law on the subject is good. The great obstacle to the successful execution of these laws lies in a fact, which many philanthropists are too blinded by prejudice to perceive, and many legislators too ignorant to comprehend, namely, that no distinction is made between intemperance the disease and intemperance the vice. While intemperance the disease remains untreated, or not properly treated, it is probable that all laws regulating the sale of liquors will prove, for the most part, ineffective. Legislators and philanthropists alike seem to be destined to grope about in darkness in their futile efforts to improve the race so far as this evil is concerned, until the medical profession asserts its prerogative, and claims its important share of the labor. It is certainly an opprobrium to our profession that it has so long remained in the background, and shown such a reluctance and disinclination to take steps towards the amelioration of the victims of inebriety.

I have brought forward this subject before this District Society because prominently in the past it has shown itself a progressive Society, and has been among the foremost of our District Societies to enlist in any needed medical reform. I have, therefore, the hope that after mature reflection and consideration of the facts placed before them the members of this Society may deem it advisable that through the State Society a movement be made for securing State legislation on this important subject.

In closing, perhaps I cannot better formulate the needs of this unfortunate class of persons, and at the same time indicate in a concise form the duties of the medical profession in relation to the subjects of this disease, than by quoting the Resolution concerning Inebriates passed by the Association of Medical Superintendents of American Institutions for the Insane:—

Resolved, That in the opinion of the Association of Medical Superintendents of American Institutions for the Insane it is the duty of each of the United States, and of each of the Provinces of the Dominion, to establish and maintain a State or public institution for the custody and treatment of inebriates, on substantially the same footing in respect to organization and support as that upon which the generality of State and Provincial institutions for the insane are organized and supported.

Resolved, That as, in the opinion of this Association, any system of management of institutions for inebriates, under which the duration of the residence of their inmates, and the character of the treatment to which they are subjected, is voluntary on their part, must in most cases prove entirely futile, if not worse than useless, there should be in every State and Province such positive constitutional provisions and statutory enactments as will in every case of presumed inebriety secure a careful inquisition into the question of drunkenness and fitness for the restraint and treatment of an institution for inebriates, and such a manner and length of restraint as will render total abstinence from alcoholic or other hurtful stimulants, during such treatment, absolutely certain, and present the best prospects of cure or reform, of which each case is susceptible.

Resolved, Further, that the treatment in institutions for the insane of dipsomaniacs or persons whose only obvious mental disorder is the excessive use of alcoholic or other stimulants, and the immediate effects of such excess, is exceedingly prejudicial to the welfare

of those inmates for whose benefit such institutions are established and maintained, and should be discontinued just as soon as other separate provision can be made for the inebriates.

RECENT PROGRESS IN PATHOLOGY AND PATHOLOGICAL ANATOMY.

BY WILLIAM F. WHITNEY, M. D.

ON THE PATHOLOGY OF DIPHTHERIA.

KLEBS¹ has made a communication upon this subject in which he considers that there are two forms of the disease that are to be sharply differentiated, both by the character of their course and the nature of the parasites which occur in them.

The first form, apparently restricted to the eastern lands of Europe, is marked by the relatively slight extension of the fibrinous exudation on the tonsils and pharynx. On the other hand severe constitutional disturbances leading to death within a few days appear very early. The micro-organisms found appear as clumps of brown-colored micrococci mixed in three layers of fibrine, also as small rod-shaped bodies placed perpendicularly to its surface. In the brain and cord, where extensive hæmorrhages have taken place, the same rods occur in the sheaths of the vessels. The pia and the gray substance are the chief seat. The severe brain symptoms and the paralysis seen in cases where recovery has taken place may be the result of such destruction of nervous tissue.

The second form occurs in Western Europe. In this the local appearances are more prominent, in some cases presenting the characteristics of what was formerly considered as tracheal croup, the contagious nature of which is now but rarely denied. The first changes are noticed on the tonsils, and from these the pharynx and trachea are quickly invaded. The initial fever is only of moderate degree, and lasts as a rule only so long as the formation of the false membrane on the mucosa progresses. On the other hand relapse as well as severe septic complications are not infrequent. Nervous symptoms fail or are seen only relatively seldom as secondary phenomena. Albuminuria occurs early, and death results either from mechanical obstruction to the respiration or from septic or interstitial inflammatory processes.

An exceedingly small bacillus is the constant accompaniment of this form. It first develops in groups in the epithelium of the mucous membrane. An enormous dilatation of the blood-vessels is associated with this as a secondary change. This leads to stasis of the blood. Immediately there follows a fibrinous exudation, and the epithelium with its adherent bacilli is raised up. These organisms form a continuous layer on the surface of the membrane, and only penetrate gradually into its interior. The stomach is rarely affected, nor has the parasite been detected in the internal organs even in those places where an interstitial process has been developed.

The possibility, of course, must be conceded that such are the effect of a chemical irritant produced by the organisms growing on the surface. On the other hand, perhaps, better methods of demonstration will furnish proof of the presence of the micro-organism in the blood-vessels, these not being colored by methyl blue or gentian that give beautiful pictures in the su-

¹ Allgem. medicin. Central-Zeitung, 13, October, 1883.

perforial layers. The bacilli are very minute, scarcely attaining the size of those found in tubercles. They usually contain two spores at the end of the rods, but on drying four or six are often to be distinguished.

The secondary result, which is attended with danger to life, is the extension of the membranous formation into the trachea. Hæmorrhagic conditions are frequently met with in the lungs, gastric mucous membrane, and subcutaneous fat tissue. These usually present themselves as irregularly banded, dark-red patches, seen on the cut surface of the organs.

With the hæmorrhage into the lungs inflammation is associated as a firm, red hepatization, accidentally joined with interstitial formation. These foci are found preferable at the lowest parts of the lungs, and seem to depend upon a paralysis of the vessels. A fibrinous exudation into the alveoli of the lungs may be associated at times with this condition of the vessels, may occasionally take on the character of a bronchial croup.

The extravasations into the subcutaneous fat are usually in the extremities, and present themselves as faded bluish spots, the diameter of which rarely exceeds one centimetre.

In the stomach where they are found they are small and very numerous, and limited to the mucosa proper.

In the territories supplied by the paralyzed vessels an interstitial deposit of cells takes place. This has been noticed in the muscular substance of the heart, in the nerves, and in the kidneys. In these latter organs, even in cases where there was marked albuminuria, such a development of cells was apt to be only slight, while a hæmorrhagic condition, such as usually occurs in acute nephritis, failed utterly. In the septic complications causing death by quick collapse there was found in the urine, together with albumen, great numbers of small, round, movable micrococci, which have been observed by Heuter and Tommasi in the blood of patients suffering from diphtheria, and described as monads.

ANATOMICAL INVESTIGATIONS ON INFLAMMATION OF THE KIDNEY AND MORBUS BRIGHTII.

Dunin¹ endeavors to explain the cause of Bright's disease and its relation to nephritis in general. There are two general questions which he considers must be answered first in order to approach the subject intelligently.

(1.) Are all forms of nephritis one and the same malady?

(2.) Where is the starting-point of Bright's disease; is it to be sought in degeneration of the epithelium or in the vessels or connective tissue?

In answering the first question attention is to be directed at first to the chronic forms. These have been divided into two classes: (1) the so-called white kidney (nephritis parenchymatosa); (2) the granular kidney (nephritis interstitialis). A third form, the small white kidney, is considered as furnishing an intermediate stage between these two both in clinical and anatomical relations.

His own studies have led him to the conclusions already reached by Weigert, that the histological changes in all forms of Bright's disease are always of the same character, and that it is only their combination which differs. These changes are (1) swelling, destruction, and proliferation (?) of the epithelium; (2) infiltration and new formation of connective tissue; (3) degener-

ation of the glomeruli; (4) thickening of the vascular walls. Even the amyloid kidney forms no exception to this, as in it all these appearances have been seen, and the amyloid degeneration is simply added to this.

Such the author considers are the common phenomena of Bright's disease, and he then takes up some of the various forms of nephritis to see if they correspond or not.

First, the forms which follow the acute infectious diseases. All authors are agreed that that which follows scarlet fever is to be regarded as a typical form of acute Bright's, and is to be placed in the closest relation to it. Of the other contagious diseases the kidneys of recurrent typhus are often to be placed in the same category, while those of typhus abdominalis are seldom so associated.

In regard to the identity of all nephritis and Bright's disease: A comparison is made between the large kidney with rather a finely granular look, which is related to the kidney of chronic passive congestion, and the so-called granular kidney of Bright's disease. The clinical picture is found to be different, and in the first case the microscope shows destruction of the epithelium, collapse of the tubules, and an insignificant hyperplasia of the connective tissue. According to him the lesions are brought about in the following manner: The epithelium is first attacked in consequence of an insufficient supply of blood (venous stasis, atheroma of the arteries, old age). This slowly proceeds, and the cells are floated off by the water, the lumen of the tubes remain patent for a time, and then finally the walls collapse. In this way an apparent increase of connective tissue results. The vessels become dilated, and the organ presents the appearance of an angioma. In this there is no evidence of an inflammatory action, and therefore it must evidently be excluded from the class of Bright's disease.

In Bright's disease, on the contrary, he considers that all the structural constituents of the kidney are affected at the same time, and it should justly be called a "diffuse nephritis."

Since it is of this nature it is inflammatory, and its commencement is to be sought in changes in the vessels followed by an emigration of white blood corpuscles into the glomeruli, the tubules, and the interstitial spaces. But how does the epithelium behave in all this? As is well known, its degeneration is constant, but in the greater number of cases this is retrogressive, and is to be referred to the same causal working that lies at the foundation of the inflammation; but, on the other hand, it is more frequently to be regarded as resulting from disturbed nutrition. So long as the whole process is confined to the disturbed nutrition of the epithelium simply there can be no talk of Bright's disease, and it is only when the addition of inflammatory disturbances of the vessels has taken place that true Bright's can be said to have developed.

ON CHANGES IN THE CORD AFTER POISONING WITH ARSENIC, LEAD, AND MERCURY.

So little has been done in the histological investigation of the changes in the spinal cord after poisoning with the above substances that Popow² has been induced to study the subject experimentally. Already it had been noticed that arsenic affected the cord, while different theories have been advanced to explain the paralysis following lead-poisoning, one considering

¹ Virchow's Archiv, Bd. xciii., s. 286.

² Virchow's Archiv, vol. xciii., p. 351.

it to be of central origin, while another located the lesion in the peripheral nerves and in the muscles. Quicksilver, on the other hand, has received but little attention in this connection.

His experiments were made chiefly upon dogs, and the first series with white arsenic. The doses were regulated so that the animals lived from four hours to seven months. The results showed that the alteration first begins in the vessels, but the nerve elements of the gray substance soon participate. In this way an acute central myelitis speedily develops, which has been designated by Webb under the name of *polio-myelitis acuta*. From its slight vascularity the white substance only takes part in the later stages, and then the picture is that of an acute diffuse myelitis. All parts of the columns are equally affected, and there seems never to be any localization.

With lead the following was a general summary of the results obtained after poisoning from seven to twenty-six days: The type of the affection was that of a general central myelitis, the most marked changes being in the parenchyma. In its further development the white substance was involved, and here the nerve fibres as well as the connective tissue stroma was implicated. In the peripheral nerves no such appearances were met as have been described by Gombault under the name of a "neurite peri-axiale." The author, however, does not deny the possibility of the occurrence of this as a later secondary symptom. He thinks that the nervous symptoms of lead-poisoning, that is, the cramps, anæsthesia, etc., can be explained by the loss of the nervous elements in the cord, and cannot be referred in any way to the peripheral nerves, the more so as the inflammatory action so quickly causes the destruction of the ganglion cells of all the groups of the gray substance.

In experiments with mercury the chloride was the preparation employed, and the animals lived from four to forty-five days. The cord presented the same general characteristics as when arsenic or lead had been employed; at first changes were to be seen only in the gray substances, then in the white columns, while the peripheral nerves remained wholly unaffected.

His results are formulated as follows:—

- (1.) Arsenic, lead, and mercury call forth marked changes in the cord which must be regarded of the character of an acute central myelitis.
- (2.) In relatively prolonged cases this is not restricted to the gray substance, but invades the white, and thus presents the picture of a diffuse myelitis.
- (3.) The peripheral nerves remain entirely unaltered under the quick action of the poison.
- (4.) The clinical symptoms find a ready explanation for what has been described above, while not one of them can be explained by an affection of the peripheral nerves.

A DISEASE OF THE SYMPATHETIC PLEXUS OF THE INTESTINE.

Blasko¹ has examined the intestines from seventy autopsies, and in two cases has found a highly characteristic change in the nerves and ganglia of the wall.

The first case was one of anæmia following childbirth, and dependent largely upon poor hygienic conditions. This became progressive, persistent vomiting came on, and coma closed the scene. At the post-mortem examination there was found fatty degeneration of the heart. The wall of the entire intestinal tract

was thin, apparently from atrophy of all the coats. Under the microscope the number of the papillæ was seen to be diminished; they were narrower than normal, and contained a brownish-black pigment at the summit. The stomach was normal.

This extreme atrophy aroused the suspicion that an alteration in the nerves was at the bottom of it, and they were examined in the following manner: Pieces of the gut were placed in a twenty-five per cent. solution of pyroligneous acid for from three to four days, when the investigations were commenced. After eight days the tissue has swollen all it could, and could then be left in the acid without fear of further change. Sections were made longitudinally and transversely through the thickness, or superficially from the surface. In this way lasting preparations could not be obtained, but if these were desired the specimen must first be hardened in a watery solution of picric acid and afterwards treated as before.

With a low power even, the ganglia and nerve fibres of both Auerbach's and Meissner's plexus, as well as the anastomosing branches, were seen to be in a condition of fatty degeneration. The ganglion cells of Meissner's plexus, which are rarely single, but usually associated together in large groups, presented the most varied pictures, from the commencement of fatty metamorphosis to the complete formation of fat drops. A medium degree was the usual condition.

The cells of this plexus are round or ellipsoidal, while their walls have a peculiar highly refractive property. The presence of fat masks this in a degree, but still they are always easy to find. The cells of Auerbach's plexus are not so easily distinguished, as they are flat, more or less polygonal plates with numerous projections placed between the circular and longitudinal layers of muscular fibres. The fatty degeneration was decidedly not so far advanced as in the cells of the other plexus. Corresponding to this the muscular fibres were also found to be fatty degenerated.

In the nerve fibres the degeneration differs according as they are medullated or not. The first sort are met with only occasionally, while the latter are in great abundance. The result, however, is the same, and when this has taken place the distinction between the two classes is lost.

This admits of an easy explanation, as it is immaterial whether the fat which is present has been formed at the expense of nerve protoplasm or of the medulla. In separate broad bands the presence of strongly refracting scales aroused the suspicion that such were remnants of nerve medulla, and therefore that such fibres belonged to that class. Among the non-medullated the picture varied according to their breadth and arrangement. The greater number of isolated branches, the ending of which was difficult to follow, were only indicated by continuous rows of fat drops, and by the cells lying in their nodal points.

The broad bands usually being in twos or threes present ordinarily a clear wall, while here and there is seen a nucleus of the sheath or the remains of an axis cylinder.

The degeneration occupied the entire thickness of the walls as far as the nervous structures were visible. The branches entering from without were the least affected, so that the disease appeared to be confined to the structures properly lying within the wall of the intestine.

The second case occurred in a woman who entered the hospital with a history of delirium tremens, and at

¹ Virchow's Archiv, Bd. xciii.

the end of the sixth day died from pneumonia. The autopsy showed, besides the hepatization of the right lower lobe, numerous fresh broncho-pneumonic foci in the oedematous tissue of three other lobes. There was also hyperæmia of the brain, chronic gastric catarrh, fatty infiltrated liver with cyanosis of all the abdominal organs. The intestinal wall was thinner than normal, but presented no marked alteration to the unaided eye. The microscopic examination showed an extreme fatty degeneration of both plexuses, even more pronounced than in the first case.

The fibres of Meissner's plexus appeared like tubes filled with fat drops resembling so closely distended chyle vessels that only their peculiar manner of branching, as well as their connection with ganglion cells, gave indication of their nervous nature. The atrophy of the mucosa was well marked, but there was an absence of pigmentation of the tips of the papillæ.

Auerbach's plexus was more gravely implicated than in the first case, and corresponding to this was the fatty degeneration of the muscular coats.

In neither case were the vessels altered.

The question to be decided is whether the affection of the nerves is primary or secondary. The probability speaks for the former. Our faulty knowledge of the function of these networks prevents a full appreciation of the value of variation from the normal type. The idea at present accepted is that we have to do with a reflex circle within the intestine itself, in which Meissner's plexus would represent the posterior cornua, and the ganglia of Auerbach's plexus the motor cells of the anterior cornua. Such an idea would be supported by the peculiar varied forms of both kinds of ganglion cells, as well as from the fact that the number of nerve fibres arising within the intestine itself is very much greater than the number of fibres coming into it from without. Thus the intestine has its own nervous system, and the external fibres are to be considered simply as regulatory.

In the intestines which came from the other autopsies no changes were found in the walls. Pigment granules were found quite constantly and in great abundance in the ganglion cells of both plexuses. These are not, however, to be regarded of pathological importance, but rather as analogous to what have been found in the cerebral ganglion cells. Further a small accumulation of fat drops is of quite frequent occurrence, and never entirely absent except in young people. These drops are much fewer than the granules which arise from degeneration, and are to be regarded rather in the light of a fatty infiltration.

R. Meier has found in the intestines of rabbits and guinea-pigs, which had been fed for a long time upon lead, a disease of the small intestine and vascular apparatus with changes in Meissner's and Auerbach's plexuses not unlike those depicted here. He mentions a sclerotic degeneration, which progressed with the development of fibrous tissue, and also seems to have found a sort of fatty degeneration of the ganglia and of the fibres of the respective networks implicated.

The first case recorded by Blasko is of clinical interest as one of a pure cachexia caused by atrophy of the intestine, and simulating in symptoms an ulcer of the stomach. Leukæmia and previous anæmia were excluded by examination of the blood and bone marrow. Absorption could only take place through the stomach, and this led to extreme weakness and anæmia, which finally ended fatally.

Reports of Societies.

ANNUAL MEETING OF THE AMERICAN PUBLIC HEALTH ASSOCIATION.

THE eleventh annual meeting of the American Public Health Association was held at Detroit, November 13th, 14th, and 15th, Dr. EZRA M. HUNT, of New Jersey, presiding. There was the usual attendance from various parts of the country, and quite a number of new names, among them several of Boston physicians, were added to the list of membership. Many State Boards of Health were represented by their secretaries or by delegates. The morning of the first day, after the transaction of routine business, was devoted to the reading and discussion of a paper by D. E. SALMON, D. V. S., of the Department of Agriculture, Washington, D. C., on

TEXAS CATTLE FEVER,

in which he dwelt at length upon the history of the disease from the time when first noted to the present day, its nature, and the methods of treatment.

It is epizootic in nature, contagious as to members of the same herd, and rapid in its progress. The spleen, kidneys, and liver are invariably enlarged, and the bladder filled with bloody urine. The Texas cattle upon their native ranges are invariably afflicted with it, and their introduction to Western and Northern markets is causing it to be known at most stock-yards. Yellow fever is regarded as a terribly fatal disease, but it is not half so fatal as this cattle fever. Texas cattle carry the contagion to foreign pastures, even as ships carry yellow fever to foreign countries, though no case ever occurred on board. Cattle carry the disease germs in their hair, in the stomach, and the alimentary canal. If our Northern cattle are to be saved from contagion, a barrier must be erected against Texas cattle.

A paper on

HOG CHOLERA,

by Dr. J. M. PARTRIDGE, South Bend, Ind., followed, in which the writer took the ground that as cholera or yellow fever prevails most in densely populated districts or in cities, so this disease has prevailed almost exclusively in the corn and pork producing regions of the Northwest; and that not on account of any climatic or inherent local causes, but because of an abundance of material on which it may be fed and developed. It may prevail at any season of the year, and while it is more contagious and fatal in summer, it is by no means exterminated or suppressed by the frosts of winter. A multitude of post-mortem examinations have revealed, in all cases, essentially the same morbid processes or pathological conditions. The seat of disease is not restricted to any organ or set of organs, but may be found in the lungs, heart, liver, spleen; in all mucous membranes, especially the intestines. In all cases the lungs and lymphatic glands are affected and generally the intestines.

A paper by Dr. W. T. BELFIELD, of Chicago, on Swellhead, Actinomycosis, in Texas Cattle, was also read.

At the afternoon session the

ETIOLOGY OF MALARIA

was the subject of papers by Dr. G. M. STERNBERG and Dr. A. A. WOODHULL, of the United States Army, both advocating the decomposition of vegeta-

ble substance as the true cause of malaria. In the discussion which ensued, Drs. BELL, of New York, ROY, of Maryland, REGAN, of Texas, and CHARLES SMART, of the National Board of Health, took part. No new light was thrown on this much vexed question.

Dr. Sternberg expressed himself unwilling to admit as proved the existence of a bacillus malarie.

The evening was devoted to addresses of welcome by State and city officials, to a long address by the President of the Association, reviewing the past history of the Association, and the present and future prospects of sanitary science. At the conclusion of the addresses the meeting adjourned to a reception and supper at the Russell House.

SECOND DAY'S PROCEEDINGS.

After the election of more new members, the subject of

MALARIA

was again taken up, papers bearing upon it being read for Drs. WEBB, of Alabama, PENN, of Tennessee, and WOOD, of North Carolina; the discussion was renewed by COL. G. E. WARING, of Rhode Island, who said, among other things, that he believes there is no connection between the Potomac marshes, soon to be filled up, and the malaria which prevails at Washington. On the contrary, he is satisfied that the malaria germs come from a swamp that was filled up some years ago. It was not drained, and the water lies there stagnant beneath the earth that was filled in. Consequently he expects an increase of malaria in Washington after the Potomac marshes shall have been filled.

DR. GUSTAVE DEVRON, of New Orleans, said that city was situated near a swamp, but is afflicted with more malarial fevers when the swamps are dry than when they are filled with water. Consequently he is satisfied that the drying up of swamp water liberates malaria germs.

DR. O. W. WIGHT thought the subject of ground water is one that should receive close attention. Drainage is, to a certain degree, a preventive of malarious diseases. As the earth dries out malaria decreases. In draining a swamp there may be an increase of malaria, but when the drainage is complete, and the earth becomes dried, there is a decrease in the disease.

Several other members took part in this discussion.

The rest of the morning session and the first part of the afternoon were taken up by a consideration of the questions of Food Supply and Adulteration of Food.

Papers on Yellow Fever and School Hygiene by Drs. HARGIS, of Pensacola, and LUNDY, of Detroit, consumed the afternoon. Dr. Lundy's paper, directed against the well-known hygienic abuses in schools, aroused some little discussion. The evening was occupied by papers on Physical Training and Physical Culture, by Drs. WATSON, of New Jersey, and D. A. SARGENT, of the Harvard Gymnasium, and by a paper on State Boards of Health, by Dr. REEVES, of the West Virginia Board.

THIRD DAY'S PROCEEDINGS. RESOLUTIONS AND REPORTS.

A resolution was adopted urging legislation by Congress at its coming session, looking to the prevention of the introduction of yellow fever, cholera, and other scourges into our Southern ports, and recommending a suitable annual appropriation to assist the National Board of Health in gathering statistics bearing upon

malarious and infectious diseases, and for a reenactment of the law of 1879, under which the introduction of pestilential diseases from foreign ports was prevented.

Another resolution was adopted asking for the appropriation by Congress of a suitable sum for the Medical Library, and for the Army Medical Museum at Washington.

Reports of the Committees on Vital Statistics and on Vaccination were submitted. The latter report, read by Dr. Abbott, of Massachusetts, opposed the largely prevailing idea that diseases are transmitted by inoculation by vaccine virus, and favored compulsory vaccination as being the only means for eradicating small-pox.

ELECTION OF OFFICERS.

The following officers were elected for the ensuing year:—

President, Albert L. Gihon, Washington. First Vice-President, James E. Reeves, Wheeling, W. Va. Second Vice-President, Erastus Brooks, New York. Secretary, Irving A. Watson, Concord, N. H. Treasurer, J. B. Lindsley, Nashville, Tenn. Executive Committee, Thomas L. Neal, Dayton, Ohio; J. D. Gatch, Indiana; H. P. Walcott, Massachusetts; Gustave Devron, Louisiana; Chas. Smart, U. S. A.; H. D. Fraser, South Carolina.

The rest of the morning session passed in the reading of a long report by Rudolf Hering, C. E., on the Removal of Decomposable Material from Households, and a paper by Dr. Oldright, of Ontario, on the Overhead Ventilation of Sewers.

At the afternoon session delegates were appointed to the International Medical and Sanitary Congresses at Copenhagen and The Hague in 1884: R. C. Kedzie and O. W. Wight, Michigan; Stephen Smith, New York; Azel Ames, Jr., Massachusetts; W. K. Newton and Ezra M. Hunt, New Jersey; J. T. Link, Indiana; George E. Waring, Washington.

Questions of drainage and sewerage took up the rest of the session. Dr. Raymond, of Brooklyn, sent a paper on House Sanitation; Dr. Van Bibber, of Maryland, one on Drainage of Level Lands; Dr. Ross, of Kentucky, a paper on Dangers of Fæcal Matters Disseminating Disease; Dr. De Wolf, of Chicago, one on Pullman from a State Medicine Point of View; Dr. Montgomery, of Chicago, on Modern Sanitation. Papers were also submitted by Dr. Jones, of New York, on Typhus Fever; by Dr. Morris, of Maryland, on Catarrhus Baltimoriensis; Dr. McCormack, of Kentucky, on Restriction of Small-Pox; by Dr. Ferguson, of Detroit, on Preventable Contagious Diseases. It will be seen that there is no lack of material for the next volume of the Association's Transactions; but the reading of so many papers prevented a full discussion of any of them. It was suggested that Cremation be a subject of discussion at the next meeting in 1884.

At the evening session, after an address by Bishop Thompson, of Mississippi, on Sane Humanity, Dr. Pratt, of Michigan, read a very long paper on The Increase of Insanity in the United States, its Causes and Sources.

At the close of the reading of Dr. Pratt's paper, after some little discussion, a resolution was adopted by a vote of thirty to one expressing the sense of the Association that legislation should be taken by Congress at its next session to put a stop to the coming to this country of the foreign criminal and pauper classes and those with an insane heredity, and, on mo-

tion, the rules were suspended for the purpose of taking immediate action upon the resolution.

The Association then adjourned to meet in St. Louis a year hence.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. W. SWAN, M. D., SECRETARY.

DECEMBER 9, 1882.

PSEUDO-MEMBRANOUS ENTERITIS.

DR. BOARDMAN stated that since his report of cases at a previous meeting of the Society, illustrating the common association of this affection with hysteria, he had met with still another case, which would serve to confirm the opinion then expressed that this pseudo-membranous discharge occurs only in hysterical subjects. This last patient, immediately after her marriage, about ten months ago, consulted a physician for the relief of backache and some trivial symptoms. She was informed that a displacement of the uterus existed, and a pessary was inserted. Finding no relief she consulted Dr. Boardman, who, upon examination, found a Hodge pessary, upside down, within the vagina, while the uterus was in excellent position, and nothing abnormal could be detected except the discharge mentioned, and some anæmia and debility. Inquiry elicited the undoubted history of hysteria, which had existed, more or less, since puberty. It is probable that the ovarian and general pelvic congestion, induced by the stimulation of the sexual functions, incident to recent marriage, was the cause of the renewal of the hysterical condition, which in this case had been in abeyance for some time before marriage.

At about the same time Dr. Boardman saw another patient who presented some obscure nervous symptoms, for which she had been treated by Dr. Denny. During the period in which these symptoms had existed she had expelled per vaginam, at each catamenial period and about twelve hours after the commencement of the discharge, a menstrual decidua, each time in two pieces. (The last specimen, of two portions, sufficient together to cover nearly the entire internal surface of the uterus, was exhibited to the Society.) It had occurred to Dr. Boardman that there might be a common origin of these two affections, but he did not recollect that they had occurred coincidentally in any of his patients. In this last case it should be stated that though the membranous pieces were considerably larger than those commonly met with, yet they were expelled with very little pain, thus suggesting the more proper term, a menstrual decidua rather than a dysmenorrhœal membrane. Nothing abnormal was found in the pelvic regions except, perhaps, an undue sensitiveness in the region of the left ovary; and it may be remarked in this connection that one theory of the origin of this affection is that it arises in an ovarian irritation which is transferred to the uterus and gives rise to this peculiar product.

DR. GOSS said that the false membrane had been discharged from the vagina and generative organs, as well as from the bowels, in one of the four cases which he had reported to the Boston Society for Medical Improvement. All were females, and not hysterical, although suffering from nervous debility. According to statistics the disease was mostly in females, but these not always hysterical.

DR. WELLINGTON mentioned the case of a young man to whom he had been called frequently, both night and day, for six or eight months, and who always had all sorts of pains and aches without obvious cause, a condition of things which, occurring in a woman, would have been called hysteria. The case passed into other hands, and Dr. Wellington learned from the attending physician that the patient, then under his care, had the pseudo-membranous disease of the intestine.

ON SUDDEN DEATH FROM THE ENTRANCE OF AIR INTO THE UTERINE VEINS.

Paper by DR. DRAPER.¹

DR. CHEEVER said that he had often been struck by the fact that air-embolism never seems to take place in ordinary surgical accidents, as cut-throat, although cellular emphysema is common in them. In badly lacerated wounds it was common to find about the knees and thighs the cellular tissue full of air; but he had never seen or heard of death from air-embolism in these cases. There was a well-known caution against this accident in regard to operations on the neck, where the large veins may be wounded while they are on the stretch, and Dr. Cheever had seen one or two instances of slight ingress of air, accompanied by a characteristic gurgling sound, resulting in gasping and a temporary interruption of the heart's action.

DR. GANNETT remarked that Dr. Draper had covered all the important points. He thought the greatest danger to the woman, the other conditions for air-embolism being present, was when she assumed the knee-elbow position, the falling forward of the abdominal contents tending to produce a negative pressure in the uterine veins.

DR. BAKER thought it rather surprising that more cases did not occur when we consider that a quite frequent method practiced by abortionists is that of the injection of air into the uterus. He had been told by a patient that she had used a Ferguson's speculum and an ordinary uterine syringe, and, by the aid of a hand-mirror, had been able to pass the nozzle of the syringe into the cervical canal, and had thus injected air into the uterus; that she had done this three times, and that on the fourth occasion, having allowed the pregnancy to continue longer than usual, she had done herself some harm by the operation. Another surprising thing was that the accident had not occurred often during the treatment of the uterus by applications of such things as impure carbolic acid, iodine, etc., even up to the third month. This had occurred to him as the most reasonable explanation of a sudden death which had occurred about four years ago in a neighboring town. The patient had been placed on the table for the removal of a sloughing fibroid. She had taken the ether very well, and the removal had been the work of but a few moments and without the slightest difficulty. The pretty broad pedicle was cut with scissors with almost no hæmorrhage. The finger was then carried into the uterus, and a second fibroid was found, of the size of a Florida orange, easily separable at the lower part, a case where enucleation seemed to present no difficulties, but scarcely was this process begun when the patient suddenly died. Dr. Baker had stripped up the fibroid for the space of about two inches in diameter. The person in charge

¹ Published in the Boston Medical and Surgical Journal, vol. cviii., pp. 3 and 28.

of the ether was an exceedingly careful and skillful man, and another assistant was present. Every attempt was made to resuscitate the patient,—hypodermic injections of brandy and of ether, nitrite of amyl, electricity, artificial respiration. Unfortunately there was no autopsy, but the most reasonable theory of the cause of death was that above stated.

DR. FIFIELD said that we had all been acquainted for years with some of the phenomena of air-embolism. In a case under the care of Dr. John C. Warren, who was operating upon a tumor of the neck, the surgeon heard the rush of air and saw his patient die. In the case of a tumor of the neck, and whose removal is followed by the entrance of air, it is said that the various fasciæ of the neck act somewhat as do the uterine sinuses. When a student at Paris at the *École pratique* Dr. Fifield heard Dumarquay advertise that he would lecture upon and demonstrate the fatal effect of the entrance of air into the veins. A large Newfoundland dog was exhibited, the jugular vein was exposed, and air was blown into its cavity. Churning of air and blood in the heart (*bruit de chemin de fer*) ensued, but the dog burst his bonds and fled precipitously home. A second dog was brought in, the jugular was inflated with great force, by a tall Scotchman, a volunteer from the audience, evidently used to the pipes. Same *bruit de chemin de fer*, as Dumarquay enthusiastically remarked. With a yell of triumph over the theories of science, the beast bounded from the table, and followed his brother down the street. Air in the jugulars had given new strength.

Dr. Fifield said it seemed to him that in Dr. Draper's cases some other element must have come into play. In the famous case of Gilson, at Plymouth, a catheter was connected with the pipe of a syringe, and an injection of air was made through the catheter into the uterine cavity. The woman died instantly. The autopsy proved the presence of air in the veins. But in the cases described by Dr. Draper, if the truth had been actually told, it was not simply in connection with the introduction of the instrument, but there must have been some absolutely rude method of introduction. Dr. Cheever had alluded to the presence of air in the tissues in the case of compound fractures; it occurred also from puncture of the wall of the chest, simulating emphysema resulting from wound of the lung by fractured rib. Some operations on the bladder and rectum had been followed by emphysema, but to his knowledge none of these cases had been accompanied by air-embolism. Why should this be an appanage of operations on the womb or its outgrowths?

DR. CHEEVER referred to a case, somewhat complicated as to the cause of the embolism, of a tumor supposed to be ovarian, but probably fibro-cystic, of the uterus. The patient was etherized, and the vagina and uterus explored by the hand only, not with violence, but still with some force, the other hand manipulating the abdomen. The finger was passed a short distance into the os and about the cervix into the cul-de-sac. Immediately following this manoeuvre the aspirating needle was put into the abdomen, where the fluid was thought to be; no fluid came. The phenomena of air-embolism then ensued; the patient became pale and livid; the respiration labored, and death very shortly followed. The first question was in regard to the ether; the tongue was drawn forward and artificial respiration vigorously performed, but this only hastened the result by mechanically sucking more air

into the heart. At the autopsy, made by Dr. Draper, all the phenomena of air-embolism, which he has described in his paper, were manifest. Air escaped at the primary incision, and was found in the heart, and traced downward to the pelvic cavity and into the uterus itself. The uterus was enlarged, and showed large, patent sinuses. The introduction of air was supposed to have been occasioned by the vaginal examination, not by the introduction of the aspirator, since a perfect vacuum had been made in Poirier's bottle, and subsequent trials proved the instrument to be in good order, and that the pumping of air into the tissues through the needle was impossible. It was Dr. Cheever's impression that there was some slight indication of lesion of the mucous membrane by violence, at the cervix, where the finger was passed. The uterus was pretty large, embracing the tumor, and had thickened walls. In so young, strong, and healthy a woman the death was very unexpected and appalling.

DR. DRAPER remarked concerning the case just reported by Dr. Cheever that the uterine wall outside the tumor was very much thinned, while the sinuses were unusually developed, but where the air entered, near the left cornu, the tumor had been separated somewhat, and there was some reddening of the part by infiltrated blood. There was an area of distinct solution of continuity of the size of a quarter of a dollar between the tumor and the uterine wall, which could not have been made by the finger, and must have been occasioned by the other part of the manipulation.

DR. BOARDMAN referred to an article in *Virchow's Archiv* in which is related a fatal case from the entrance of air into the veins in the immediate vicinity of a gastric ulcer. The fatal effect was brought about usually, in the conclusions of the writer, by interference with the action of the valves on the right side of the heart. It was a curious fact that in some of the experiments made air injected under a certain pressure into the vein of one leg made its appearance in the corresponding vein of the opposite extremity.

DR. DRAPER stated that cases are reported where the air has been found in parts of the systemic circulation remote from its point of entrance, so that it must have gone through the pulmonary circulation.

DR. C. ELLERY STEDMAN exhibited a drawing of an instrument once the property of an abortionist, which had come into the hands of the late Dr. C. C. Holmes. It consisted of a sharp, pierced metallic catheter, to which an air-bag was attached.

NEW YORK ACADEMY OF MEDICINE.¹

MEETING of November 15th, *continued*.

The paper of the evening was read by DR. FRANCIS DELAFIELD, on

TYPHOID FEVER IN NEW YORK.

After alluding to the fact that all who were engaged in practicing in New York at the present time felt an interest in the study of typhoid fever, on account of the constantly increasing number of cases which had been met with during the past year, and after showing that statistics, although dry, were sometimes wholesome and necessary, Dr. Delafield proceeded to mention some figures in reference to the number of deaths from the disease occurring in the city during the past few

¹ Concluded from page 497.

years. For some years prior to 1863 the yearly mortality averaged from 100 to 200 cases. Between 1863 and 1866, when typhus fever prevailed in New York, the yearly mortality ran up to from 500 to 600, and since then the average number of deaths per year had been from 200 to 400. In 1879 there were 178 deaths; in 1881, 446; and in 1883, up to October 1st, 274 deaths. In New York, as in most other places, the disease was most prevalent during the months of August, September, and October; though no month of the year was exempt from it.

From January 1, 1878, to October 1, 1883, there were treated in the hospitals of New York 1305 cases of typhoid fever, and in these different years there was a variation not only in the whole number of cases but also in the mortality. In 1878 there were 124 cases, with twenty-seven per cent. mortality; in 1879, 114 cases with twenty per cent. mortality; in 1880, 110 cases, with thirty per cent. mortality; in 1881, 319 cases, with twenty-two per cent. mortality; in 1882, 313 cases, with twenty-three per cent. mortality; and in 1883, up to October 1st, 190 cases, with a mortality of twenty-six per cent. From this it would be seen that the greatest relative number of deaths occurred in 1880, and the smallest in 1879.

In noting the age of the patients treated it was necessary to take into consideration the fact that in the various hospitals referred to the population, as a rule, consisted entirely of adults. The ages were as follows:—

From 5 to 10 years	49 cases.
From 10 to 20 years	336 cases.
From 20 to 30 years	604 cases.
From 30 to 40 years	186 cases.
From 40 to 50 years	77 cases.
From 50 to 60 years	16 cases.
From 60 to 70 years	2 cases.
Over 70 years of age	4 cases.

The ordinary rule of typhoid, of preferring young adults, was, therefore, observed in these cases; by far the largest number occurring in patients between twenty and thirty years of age.

After alluding to the difficulty of stating with certainty anything in regard to the ætiology, especially as many of the cases originated outside of the city, Dr. Delafield proceeded to speak of the pathological changes observed at the autopsies recorded. The regular intestinal lesions of typhoid were present; the changes, even in the worst cases, being confined to the agminated and solitary glands. Perforation occurred in only a small number of cases, and in two of these it was through the walls of the vermiform appendix. The colon was involved in only a few instances. The mesenteric glands were swollen in all the cases; but suppuration of these glands was found in only two cases. The spleen was soft in all cases. It was sometimes enlarged, sometimes of normal size, and sometimes smaller than normal. In a single instance (the patient being a boy of eight years) the spleen was ruptured, and there was a large extravasation of blood into the peritoneal cavity. The liver in many cases was enlarged, and the kidneys also often exhibited swelling with degeneration of the epithelial cells. In such cases there was sometimes albumen in the urine during life, and sometimes not. The lungs exhibited a variety of changes. Severe bronchitis and broncho-pneumonia existed in only a few cases, and lobar pneumonia was found in two cases. Hypostatic congestion of the posterior part of the lungs was very common; but extreme hypostatic

congestion was seldom met with. Granular and waxy degeneration of the voluntary muscles of the abdomen were seen in only a very few cases, and in the majority of cases the heart was firm, with unaltered muscular structure. It was evident, therefore, that the anatomical type of the disease was not a severe one; neither the characteristic or the accessory lesions being more than fairly marked.

The study of the symptoms Dr. Delafield had made from 102 undoubted cases of typhoid fever treated at the hospitals during the past five years. A distinct prodromic period was noted in only eighteen cases. This varied very greatly in duration, but the symptoms (of which bronchitis was quite frequently one) were much the same in all. The character of the invasion was ascertained in eighty-three cases. In thirty-seven a chill occurred on the first day; sometimes mild and sometimes severe. This was sometimes repeated on successive days. It was followed by febrile movement, usually accompanied by headache, nose-bleed, and diarrhœa. There were forty-four cases, altogether, in which diarrhœa was one of the first symptoms. In three there was blood in the passages from the first. In fifteen cases headache and fever were the first symptoms, and in six bronchitis was the principal difficulty during the first week. Pain in the right iliac fossa or over the abdomen was noted in a number of the cases.

The record of the temperature during the first week was more incomplete than at any subsequent period. In the cases where it was kept, however, it was noticeable that the temperature did not rise according to the fixed curve of typhoid fever, but was, as a rule, more or less irregular. It was frequently found that the transfer of the patient to the hospital produced a very decided, though temporary, increase in temperature. In some patients there were morning chills followed by fever, and this by sweating, all repeated a number of times during the first week, and in others there was a sudden fall of temperature lasting six, twelve, or twenty-four hours.

In the second week the temperature curve approached more nearly that of a regular continued fever. In some cases there were decided remissions in the morning (the temperature falling as low as 99° F.), and in others the morning temperature was the highest. In some instances convalescence was established after the fifteenth day, and in others there was a temporary remission at this time, the fever then going on for several weeks longer.

In the third week the temperature was much the same as in the second, while in the fourth there was a more decided fall in the morning. In some cases after falling for two or three days in succession it would rise again, and continue high for a week or two more. As a rule the temperature varied according to the severity of the disease, but this was by no means always the case. In mild cases the temperature was sometimes as high as 103° F. to 105° F., and in severe ones sometimes as low as 100° F. to 103° F.

The pulse varied greatly, of course, in different patients, and was generally more rapid, and sometimes dicrotic, in the third week. It was sometimes both feeble and slow, and a very rapid pulse was usually an unfavorable sign. In cases where the patient died with low temperature the pulse was apt to be feeble and rapid. The appearance of the facies was generally characteristic.

The tongue in most of the cases was at first coated down the centre with a thick white fur, and afterwards became brown and dry. In some, however, it remained clean from the first, but became dry and fissured. The moistening of the tongue was always a favorable sign. Delirium was well marked in forty-one cases, and was sometimes so severe that it was liable to be mistaken for acute mania.

Diarrhœa, as had been stated, occurred very early in a large proportion of the cases. There was diarrhœa in eighty-two cases altogether, and in fifty-one it continued throughout the attack. Constipation was noted in eighteen cases, and was apt to be associated with excessive tympanites. The characteristic eruption was found in forty-four cases, and Dr. Delafield remarked that during the present autumn he had found it much more common than had usually been the case for the last five years in New York.

Complications. Hæmorrhage from the bowels was present in twenty-three out of the 102 cases, and in six of them seemed to be the immediate cause of death. The characteristic hæmorrhage of typhoid fever, due to ulceration, was met with in the second week in most of the cases in which it was noted. In three cases, however, at the very outset of the disease the diarrhœal passages were streaked and mixed with blood, and this could not, of course, have come from ulcers in the intestines. In two cases there was a constant bloody discharge from the bowels which came on late in the disease, and which resembled the hæmorrhage met with in cancer of the rectum. In those cases in which the characteristic hæmorrhage of typhoid fever was noted a well-marked fall of temperature usually took place within a few hours after its occurrence, but there were many exceptions to this. Hæmorrhage was always an alarming symptom, and out of the twenty-three cases in which it was seen only nine finally recovered.

In three cases a well-marked pustular eruption occurred covering the whole body, and in five there was suppurative inflammation of the middle ear. Severe pharyngitis with the exudation of false membrane occurred in one case, and a moderate degree of catarrhal pharyngitis in a large number of instances. Bronchitis of severe type or broncho-pneumonia was observed in twenty-four cases, in some of which it was the immediate cause of death. Slighter forms of bronchitis were very common. Lobar pneumonia occurred in two cases, and in both was apparently the cause of death. Enfeebled heart action was frequently met with.

Peritonitis was observed in only four cases. In two it was caused by perforation of the small intestine, and in one of the vermiform appendix from ulceration, and in one it was due to inflammation of the mesentery. All four proved fatal. Dysentery was noted in five cases, four of which recovered.

Duration. In sixty-one cases which recovered (exclusive of relapses) —

1 case recovered in	16 days.
4 cases recovered in	18 days.
6 cases recovered	at end of third week.
19 cases recovered	at end of fourth week.
12 cases recovered	at end of fifth week.
4 cases recovered	at end of sixth week.
4 cases recovered	at end of seventh week.
1 case recovered	at end of eighth week.
9 cases recovered	at end of ninth week.
1 case recovered	at end of tenth week.

The largest number of recoveries, therefore, took place at the end of the fourth and fifth weeks. In cases lasting longer than the fifth week there were often periods when the temperature would fall, and, after remaining low for a time, would rise again. Well-marked relapses occurred in only seven cases, and they all recovered.

Of the 102 cases, thirty-four proved fatal; fifteen of these being directly attributable to the disease itself, and the rest to complicating conditions. In most of the former cases the temperature ran high (104° F. to 107° F.), but, as a rule, was not continuously so up to the time of death. The pulse was feeble, and usually rapid. In six cases death resulted from hæmorrhage, in one from syncope, in four from peritonitis, in three from bronchitis, or broncho-pneumonia, in two from lobar pneumonia, in one from rupture of the spleen, and in one from dysentery during convalescence; while one patient died from collapse (the temperature falling to 95° F. in the rectum), a few days after a very thorough sponging with ice water and lumps of ice.

Treatment. In mild cases the patient was simply put to bed, and placed on milk diet, some of the hospitals using peptonized milk in preference. Alcohol was given in some shape by some physicians, without exception. By others it was reserved for cases with feeble heart-action. Digitalis, convallaria, and caffeine, were also used as heart tonics. In some hospitals quinine was given in nearly every case, while in others it was scarcely used at all. In some it was employed only when the temperature was as high as 103° F. General bathing seemed to have been about abandoned during the past year; although before that it had been used quite extensively. Sponging the whole body, the Kibbie cot, and the cold pack were still employed to some extent in some hospitals; but in others the use of cold water as a means of reducing temperature was about entirely abandoned. For tympanites the use of turpentine was still the standard treatment. For intestinal hæmorrhage opium and ergot were employed, and for restlessness and sleeplessness opium was still much used by some. For diarrhœa the agents relied upon were opium, opium with bismuth and pepsin, and, in some hospitals, acetate of alumina. In one hospital large doses of calomel were given, if the case was seen early, in the hope of aborting the disease. Salicylate and benzoate of soda and tincture of iodine, combined with carbolic acid, given with the idea of counteracting the typhoid fever poison, were but very little used.

DR. BARKER remarked that the paper seemed to him the most exhaustive analytical paper on typhoid fever since Murchison's contributions, and called attention to a number of points which had struck him during the reading of it, and which he would suggest as topics for discussion.

DR. LOOMIS said he had hoped that Dr. Delafield would give a definition of typhoid fever, but though he had not done so, the symptoms which he had described in this carefully prepared record of typhoid fever in New York were not those which we had been led to believe characterized the disease in other countries. Liebermeister's description, for instance, would not at all tally with Dr. Delafield's. After mentioning the principal characteristic symptoms as described in the books, namely, the regular curve of temperature and the peculiar eruption and diarrhœa, he said that we must either regard the fever met with in New York as a simple continued fever attended with typhoid

symptoms, or else throw away all idea of typhoid fever as a distinct and special disease. In the course of his remarks he gave a *résumé* of the cases of typhoid which had been under his care at Bellevue Hospital since the last week in September, as prepared by his house-physicians. They were seventeen in number, and constipation was noticed in thirteen of them. The highest range of temperature was 105.4° F., and the average range was 101.25° F. The eruption existed in only four cases, and diarrhoea in four. Hæmorrhage occurred in two cases, and peritonitis in two. In each of the latter there were ulcerations in the large intestine as well as the small. Four of the cases proved fatal, but three of these patients died within three days after admission to the hospital.

DR. KINNICUTT spoke particularly of constipation, and advised frequently repeated small enemata of thin gruel for its relief. Out of eighteen cases which had been treated at St. Luke's Hospital during the present season, constipation existed in seven, and diarrhoea in nine. He then said in regard to relapses that he believed them to be wholly independent of errors in diet or other incidental causes, and in concluding his remarks advised great caution in the use of alcohol in typhoid.

DR. JANEWAY thought that the statistics of the health department showed conclusively that typhoid had not of late been more prevalent than formerly, especially when the great increase in the population of the city was taken into consideration. Unlike Dr. Loomis, he believed that typhoid fever was the same disease everywhere; for, however greatly the symptoms might vary, the lesions were always the same. Both Liebermeister and Murchison admitted that atypical cases occurred. He spoke at considerable length of the specific origin of the disease, and referred in confirmation of this to the history of various outbreaks of the fever with which he was familiar, especially at the Roman Catholic Half Orphan Asylum, and the Deaf and Dumb Asylum in New York, at Princeton College, and at Fort Washington. In regard to the eruption of typhoid, he agreed with Dr. Delafield that it was particularly well-marked this season, and said that he had not met with a case of the fever in an adult after the tenth day in which it was lacking.

DR. T. A. McBRIDE, after speaking of the milder forms of typhoid as met with at the dispensaries and hospitals, mentioned that he was in the habit of treating the high temperature incident to the disease with kairin. If the temperature was 103° F., or higher, he gave seven grains of the drug every hour, and if it was not higher than 102° F. he gave three and a half grains every hour. This plan was invariably successful, but he never brought the temperature lower than 101° F. for the reason that when this was done the patient was apt to have a chill, and the temperature then rose rapidly again.

After brief remarks by Drs. Barker, Pinkney, and Fruitwight, DR. DELAFIELD closed the discussion. That the disease did not always have typical symptoms, he said, was well known, and that was the very reason why he had thought it would be well to bring these cases together. Liebermeister, he thought, had sacrificed truth in order to give a clear and definite description of the disease, and thus had presented an exaggerated picture of it. But the lesions were the characteristic feature of typhoid, and however they might differ in degree, they were always the same in

kind. As to constipation, he considered it a positive evil to the patient, and always gave laxatives for it, during the first week, when they were required. After that he thought enemata were better.

Recent Literature.

Die Anämie. Von S. LAACHE. Universitäts-Programm für das 2 Semester, 1883. Christiania. 1883.

Dr. Laache received in 1881 a gold medal from the University at Christiania, Norway, for a monograph upon the Condition of the Red Blood-Corpuscle in Secondary Anæmias. The present volume is an amplification of that essay, the work for both having been carried on in the physiological laboratory at Christiania under the general supervision of Dr. Worm Müller, Professor of Physiology at the University. The blood and its corpuscles are considered in the normal state and in anæmic conditions, which latter are divided into secondary and primary, and supplementary primary (a heading which comprises leukæmia and pseudo-leukæmia). This work is published in German, contains 276 octavo pages in addition to a large number of charts, and is very *eingehend*.

Inquiries into Human Faculty and its Development. By FRANCIS GALTON, F. R. S. New York: Macmillan & Co. 1883.

This volume is composed of numerous memoirs by the writer on various subjects which have been scattered through the pages of different periodicals between the years 1863 and 1883, and are now brought together in substance and in logical sequence as having an underlying connection.

With the name of Mr. Galton, and with some of these memoirs, the readers of the JOURNAL have already become familiar through its pages, and those who are interested in such subjects as the Relative Power of Nature and Nurture, Composite Portraiture, Visualized Numerals, Physiognomy of Phthisis, Anthropometric Laboratories, would do well to consult this book, where these subjects are correlated with others and with each other, and where much of what the author has to say about them is revised and rewritten. The book certainly answers the chief claim made for it by Mr. Galton — it is suggestive.

The Diagnosis and Treatment of Diseases of the Ear. By OREN D. POMEROY, M. D., Surgeon to the Manhattan Eye and Ear Hospital, etc. With One Hundred Illustrations. New York: Bermingham & Co. Price \$3.00.

A work of some four hundred pages very well arranged and well written, not too scientific, and containing some few inaccuracies of reference, due to an insufficient study of the previous literature of the subject. It is a very good guide for the young or very busy practitioner.

The illustrations of instruments and apparatus are good, as also are some few of the anatomical plates, but those relating to pathological conditions are imperfect, and scarcely serve their purpose.

Medical and Surgical Journal.

THURSDAY, NOVEMBER 29, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

THE REGULATION OF IMMIGRATION.

WE last week took the occasion of a legislative hearing on the subject to say something about the desirability of making separate provision for the criminal insane. This is an important question, but an even more important one is whether anything can be done by the General or State Governments to diminish the number of this class by guarding against the introduction into the country of the materials from which the criminal insane, as well as the other insane, are largely recruited. This question was introduced at the late meeting of the American Public Health Association at Detroit by a paper from Dr. Foster Pratt, of Michigan, on the Increase of Insanity in the United States, Its Causes and Sources, which is referred to in our brief report of the meeting in another part of this issue of the JOURNAL. Dr. Pratt's paper is based upon the United States census for the decades ending in 1850, 1860, 1870, 1880; the imperfections in which, as far as such exist, are equally applicable to all except the last, and do not invalidate their usefulness for purposes of comparison. If the writer's figures are correct, and we have no reason to question them, one can hardly avoid accepting his conclusions, especially as they tally with those to which *a priori* reasoning would lead.

"(1.) Beginning with 1860, while the foreign born population had increased, since 1850, nearly 100 per cent., the foreign born insane had increased 181 per cent.

"(2.) At the close of the next decade, in 1870, the total foreign born had increased only about thirty per cent., but the insane of this class had increased nearly 100 per cent.

"(3.) In 1880, the foreign born had increased less than twenty per cent., but their insane had increased 150 per cent.

"(4.) A statement of the proportion of insane to each class of population — native and foreign — at each census, shows very clearly the relative rate of increase.

"In 1850, of native population, there was one insane in 1545; and of the foreign born one in 1095.

"In 1860, of native born, the proportion was one in 1559; and of foreign born one in 717.

"In 1870, native born furnished one in 1258; and foreign, one in 497.

"In 1880, native population shows one insane to 662; and foreign born, one in 250.

"Thus it becomes manifest, that while the proportion of native insane to native population remained nearly the same in 1850, 1860, and 1870, the proportion of foreign insane in the foreign element rapidly increased from one in 1095 in 1850 to one in 497 in 1870; and when we reach the approximately accurate aggregates of 1880, we find the native insane amount to one in 662 of native population, while the foreign born insane are one in 250 of foreign born population; and that nearly one eighth of the aggregate population furnishes nearly one third of the aggregate insane."

Again:—

"(1.) That the proportion of insane to native white population, in the Northern States, is one in 597; in the Southern States, one in 660; and in the District of Columbia and Territories, one in 748.

"(2.) That among the foreign white the proportion in the Northern States is one in 248; in the Southern States, one in 283; and in the District and Territories, one in 236.

"(3.) That among the colored races, the proportion in the Northern States is one in 545; in the District and Territories, one in 680; and in the Southern States, one in 1235.

"(4.) That the average proportion of insanity among native whites in the entire United States is one in 618; among foreign whites, one in 250; and among the colored races, one in 1097; and that the total average for the entire country, of all population, is one in 545.105."

Believing in his figures, always be it understood for purposes of comparison, and accepting the conclusions to which they lead, namely, that there has been a marked increase of insanity among our native population, but a still more exaggerated increase among our foreign population, Dr. Pratt asks, what we are going to do about it.

The native must learn to adapt his life to his vital as to his financial resources; to live at a lower pressure. On the other hand, and this is the important point, the foreign element from which the inmates of our asylums are so largely drawn — the debauched and diseased, the criminal, the pauper classes — must be kept out of the country, not by prohibiting their landing here, but by preventing their embarkation on the other side of the Atlantic. Without charging foreign governments with complicity in this matter of "assisted emigration," which without the name has undoubtedly been going on more or less vigorously for many years, those who know anything about public paupers and the public sick at home have no difficulty in realizing the process which takes place. It is but necessary to call to mind the relations of one State to another, of one town to another, of one hospital, even, to another.

It is suggested that the general government attach agents to our consular offices at certain foreign ports whose certificates should be required from all immigrants, and that it should be the duty of such agents to detain suspicious emigrants, and look up their antecedents. Some such system does not seem to us necessarily impracticable, and the mere appointment

of agents would act to a certain extent as a check, just as a light in the window discourages a burglar. We are a young nation, and a strong one, but there is a limit to the amount of debased blood, as to the amount of debased coinage, which can be introduced into the national circulation with impunity.

Congress passed an act under date of August 3, 1882, which was intended to control the landing of pauper immigrants, but, unfortunately, it is inoperative, no penalty having been provided for its violation. The law states, after providing that certain officers or boards in States shall be designated by State governors to supervise immigration, "*their officers shall be authorized to go on board of and through any such ship or vessel, and if on such examination there shall be found among such passengers any convict, lunatic, idiot, or any person unable to take care of himself or herself without becoming a public charge, they shall report the same in writing to the collector of such port, and such persons shall not be permitted to land.*" In compliance with this law the collector forbids the landing of such persons, but without avail in consequence of want of penalty to enforce the order.

Hence we are glad the Association voted to memorialize Congress that legislation be adopted to check, not merely the landing in, but the coming to this country of the foreign criminal and pauper classes, and those with a pronounced insane heredity, for under existing conditions the declaration of Dr. H. P. Walcott, of this State, that "it is an indisputable fact that our poor-houses are filled with foreign paupers, our hospitals with foreign cripples, and our insane asylums with foreign insane persons," cannot be dismissed as a mere rhetorical flourish.

DIET IN DIABETES.

PROFESSOR AUSTIN FLINT, in a recent lecture on diabetes, speaks of the difficulties to be encountered in effecting a suitable anti-diabetic diet. The alimentary regimen of this disease consists in withholding from the food, almost entirely sugar, in any form and all the starchy constituents of food capable of being transformed into sugar. This is a matter of great difficulty, which requires the constant supervision of the physician, and can only be accomplished by the latter placing before the patient a list of all articles of food which are permitted, specifying them, and also all articles of food which he must not take. The patient should have such a list before him in the hand-writing of his physician, and such articles should be selected from the allowable ones as to make a variety from day to day, and so prepared by the artifices of cookery as to make them satisfactory. This can be done, but it requires patience and it requires care on the part of the patient or somebody else, and it requires means. The poor man can hardly afford the bill of fare or the severe restrictions of the diabetic hygienist.

The article of food which will cause most trouble is bread, and diabetics realize the force of the statement that bread is the staff of life. Frequently they

say that they care little for bread, that they can get along very well without it, but they do not find it so after a while. Therefore there have been numerous substitutes for wheat flour bread, but few of which are to be commended. There is what is called diabetic flour, which is bran very finely ground so as to divest it of all rough particles, but it has no nutritive value whatever, and is, as Dr. Flint says, no better than sawdust. Dr. Flint commends as more satisfactory than anything which he has before tried the gluten bread prepared by the Health Food Company of New York. It is not entirely devoid of starch, but it is so prepared that it is not deprived of the agreeable qualities of ordinary bread, and helps render the animal part of the daily dietary more acceptable.

Bouchardat is doubtless the great authority on the dietary regimen of diabetic patients, as stated in the lecture which we printed last week. While rigidly excluding the long list of starchy and saccharine aliments, he allows the diabetic to eat without fear meat of all kinds, brown or white, broiled or roasted, seasoned with any sauce pleasing to the palate, provided there be no flour or sugar in it. He especially commends the flesh of carnivorous animals, and advises their trying cat, dog, and fox! The liver should not be eaten, and the fat of meat should be as far as possible avoided. All sorts of fish, shell fish, and lobsters are permitted. As for the green succulent vegetables there is a wide latitude of choice; spinach, endives, lettuce, sorrel, asparagus, artichokes, cress, dandelion, etc., being good for diabetics, and salads may be allowed, with a full complement of oil and hard boiled eggs. For drinks, besides a moderate amount of good claret or Burgundy, which may be daily taken, brandy and soda water may be used, and fresh beef tea, which latter is a capital quencher of thirst.

Many of the articles allowed by Bouchardat are not altogether devoid of sugar or starch, but the quantity is so small as not to be considered dangerous, and the *menu* of this great authority has not been improved by any of the subsequent writers on this disease, if we may credit Chambers, from whose *Manual of Diet* we quote.

JUDICIAL MURDERS.

THE English medical journals had hardly ceased protesting against "the judicial murder" of the lunatic Gouldstone before they found similar cause of complaint in the sentence of death passed upon James Cole for murdering his child, three years and a half old, by lifting it by the legs and dashing out its brains against a wall. Cole was not under the influence of liquor or of passion at the time. He was certified as insane in 1877, and was committed to the county workhouse a second time in 1879. He had epileptic relatives, and was himself addicted to drink. He had delusions of persecution, that he had been poisoned, and that he was to be killed, for a sufficient length of time to have become mentally impaired, and suffered from a form of insanity almost absolutely incurable, and under the influence of which crimes are quite certain to be committed if there are opportunities enough afforded.

The officers in the jail testified that the prisoner behaved like a sane man. His son and Dr. Jackson gave positive evidence of his insanity. Other witnesses in his behalf were not called, although they were in attendance. Dr. Jackson stated, in a letter to the *Times*, that proofs which would have convinced the jury of the prisoner's insanity were in the possession of the Crown at the time of the trial, but that they were willfully withheld. The defense was, at all events, very summarily disposed of.

Mr. Justice Denman, in passing sentence, said that the evidence established the fact that the prisoner was laboring under delusions, but that he knew what he was doing, and knew that he acted contrary to law; that he committed the act under the influence of passion which had got possession of his mind from want of sufficient control. The knowledge of right and wrong has been not seldom made the test of responsibility in the courts, of late years even, and England is far behind France, Germany, Austria, and this country in that respect.

MEDICAL NOTES.

— Col. Robert Murray, assistant surgeon-general, and senior surgeon of the service, has been appointed by the President surgeon-general of the army.

— Dr. E. N. Whittier has been appointed by the Commissioner of Pensions a member of the Board of Pension Examiners for Massachusetts.

— Dr. Depaul, the well-known professor of obstetrics and physician to the Lying-In Hospital of Paris, is dead, at the age of seventy-three.

— Turgenev, the Russian novelist, is said to have had a brain weighing sixty-three ounces.

— Mr. John P. Howard has announced his intention of giving a new building for the medical department of the University of Vermont, at a cost of about \$40,000. The old building will be refitted for a gymnasium at the expense of the same gentleman, who will then have expended more than \$400,000 for the university and the city of Burlington in ten years.

— F. P. Atkinson reports, in the *British Medical Journal*, September 15, 1883, the case of a lady of good position, who was married at sixteen, and died at sixty-four, who had thirty-nine children by the same husband. There were thirty-two females and seven males, with only two sets of twins. All the children attained their majority.

— An item from *L'Union Médicale* shows that certain principles of dealing with the foibles of men are common the world over. It seems that a mysterious kind of personage installed himself as a doctor in the most frequented part of the Faubourg Montmartre. Admission could only be gained to his presence after infinite questionings. His name was a foreign one, and all his servants were bound over to secrecy. His consultation room was, in consequence of all this, besieged from morning to night, until at last the attention of the police was attracted. A *commissaire* called upon him and demanded an inspection of his diplomas, expecting to find him pale and trembling at the request. Nothing of the kind. The suspected

practitioner, all smiles, opened a drawer of his bureau and exhibited to his visitor documents which were perfectly authentic. "And now that you have quite assured yourself, M. Commissaire," said the doctor, "pray do not betray me; for if my patients only get to know that I am a mere Doctor of the Medical Faculty of Paris, I shall see no more of them."

— There is a case reported in *Schmidt's Jahrbücher* of poisonous symptoms following the use of an injection of a four per cent. solution of boracic acid for chronic diarrhoea, and the *Medical Record* reports a death supervening upon its external use in an ulcer. It would appear that boracic acid is not as harmless as is usually supposed.

— The new Primate of England has already succumbed to overwork, and been obliged to take complete rest. Several others of the English bishops are in the same condition, and it is said that as a body they are much overtaxed in strength by their duties.

NEW YORK.

— The committees of the Saturday and Sunday Hospital Association having in charge the formation of trade auxiliaries met on the 8th of November, at St. Luke's Hospital, when encouraging reports were received from the various auxiliaries already organized, and a plan was adopted providing for the issuing of coupons by the Hospital Association to all trade auxiliaries, these coupons to represent dollar for dollar the amount contributed by each auxiliary, and entitling them to that extent to draw on the hospitals within the Association for service in behalf of any sick poor the auxiliaries may recommend.

— The Central Organization of the New York State Medical Association to Uphold the National Code of Ethics has just published a catalogue of the members of the medical profession in the State in which the vote of each individual on the codes of ethics is recorded as far as it has been possible to ascertain the facts of the case. It contains the names of 5219 physicians, which are classified as follows:—

For the National Code	2424.
For the New Code	943.
For no code	210.
Unclassified	31.
Uncommitted	1611.

The unclassified, it is explained, have responded to oral or written inquiry, but have not signified exactly where they stand, that is to say, their answers do not entitle them to be included under any one of the first three headings. The uncommitted have not been heard from. The numerical exhibit of the vote of the State is by county, the names of the fifty-nine counties being arranged in alphabetical succession. In the county of New York the figures are as follows:—

For the National Code	770.
For the New Code	423.
For no code	58.
Unclassified	10.
Uncommitted	445.

And in the county of King's (Brooklyn) as follows:—

For the National Code	232.
For the New Code	91.
For no code	31.
Unclassified	5.
Uncommitted	164.

The catalogue is open for correction, and is accompanied by a circular in which the Council of the Association request that all errors in it may be pointed out. Their desire, it states, is to know the whole truth concerning the attitude of the profession in respect to the ethical controversy, and they deem this a fair and equitable method of ascertaining the will of the entire profession of the State. "The question to be solved," it continues, "is whether the profession wishes to retain its allegiance to the American Medical Association or to disfranchise itself therefrom by sustaining the New Code or by abrogating all codes of ethics. It is believed that the time has come for every member of the profession in the city and State of New York to declare himself on one side or the other—for or against the National Code. Therefore, those who are still uncommitted are earnestly appealed to for their decision."

Miscellany.

OBSERVATIONS ON THE THERAPEUTIC RESULTS OF HYPNOTISM.

DE GIOVANNI has recently published, in a reprint from the *Gazetta Medica Italiana*, some observations on the above subject which are thus summarized in the *Centralblatt für klinische Medizin*, No. 42, 1883:—

Giovanni reported five cases in which he had employed hypnotism for therapeutic purposes. Four of the patients were females, with markedly nervous constitutions, the fifth a young man of eighteen years. In the first case there was a circumscribed painful spot in the lower portion of the dorsal spine persisting after a contracture of the lower extremities that had been cured by massage; in the second an obstinate nervous vomiting; in the third a nervous affection of a very diverse and changeable character consisting of contractures, neuralgias, anæsthesias, etc., which, according to the opinion of the reporter, did not depend upon hysteria.

In the two first cases Giovanni succeeded in hypnotizing the patients at the first attempt while he caused them to look at the point of his finger held fourteen to fifteen centimetres distant from their eyes, and a little above their level. With the third patient in the first sitting, although it lasted an hour, no sleep occurred, and but little in the second, but in the latter some tremulous movements of the legs took place without, however, the patient's being conscious of them. In the third sitting she came into an evident hypnotic state. In all three cases complete cure followed after two to four weeks of treatment, whereas they had resisted every other treatment. The sittings took place from one to three times daily. The fourth patient suffered from alopecia areata and a peculiar affection of the skin. Giovanni wished to excise a bit of the skin for microscopical examination, and hypnotized the patient with that object. He was able to perform the little operation without the patient's experiencing the least pain. For a similar purpose he hypnotized the fifth patient, who was suffering from an acute, exceedingly painful coxitis, and on whom a bandage was placed during his sleep.

The phenomena observed were in all cases the following: At first accelerated movements of respiration

and movements of swallowing occurred. The pulse, too, became quicker. Then the lids closed, and the eyeballs turned upward; then quiet sleep during which the tendon reflexes were exalted, but the neuromuscular excitability not enhanced. Complete muscular relaxation and cutaneous anæsthesia followed, yet needle-pricks called forth lively reflex movements. It was noteworthy that after the awakening sharp pain was experienced in the place of the puncture, and circumscribed reddening of the skin appeared as after a flea bite. The lids were convulsively shut during the sleep. The sense of hearing was the least altered. The four patients conversed during their sleep as if they had been among their own families. After fourteen to fifteen minutes' duration of the sleep awakening occurred spontaneously or after blowing upon the face. Except for a transient feeling of heaviness in the head the condition of the patients was good after awaking. In the fifth case at first sleep came on, but no anæsthesia; this became complete after Giovanni had employed a moderate short pressure on the eyelids and the roots of the nose, and had rubbed the skin of the forehead. In like manner could the hypnosis be hastened by a slight rubbing of the eyeball.

Giovanni is of the opinion that in the hypnotic sleep the conduction to the brain is completely severed, while that to the spinal cord is not disturbed, as is indicated by the persistence of the reflex movements. The appearances observed after the needle punctures are explained by extraordinary excitability of the peripheral nerves and of the spinal reflex action, as well as by vaso-motor paralysis at the punctured spot during hypnosis. He calls for further therapeutic researches on the safety and efficacy of hypnotism.

PREHISTORIC TREPHINING.

In *Science*, August 3d, is a résumé from *Bull. Soc. Anthropol.*, Paris, of the novel experiments of L. Capitan calculated to throw light on this much discussed subject. Many years ago Dr. Charles Rau, wishing to know how long it would take a savage to bore a hole through a hard rock with a wooden spindle, using sand and water, actually made the experiment, and has put on record his experience. M. Capitan has proceeded in the same way respecting prehistoric trephining, testing the various methods of boring and of removing a rondelle or fragment of bone. The experiments on the skulls of the dead were to study the methods, the difficulties in the way of the operation, and the time required. It is the trephining of the living among savages and the fatality of the result that most interest the student, therefore M. Capitan continued his researches upon living canine subjects. The first experiment was upon a small spaniel. The skin of the head and temporal muscle were removed, and the trephining was practiced upon the antero-superior portion of the right parietal. The operation was not very painful, and in twenty minutes a rondelle of bone was removed. There was little hæmorrhage, and the meninges were not wounded. After a few days the spaniel was as lively as ever. Two other dogs were subsequently treated with like success. Just what the method and amount of cicatrization might be, after such primitive operations, will be known when the autopsy of the subjects takes place in the future.

THE NEW BUILDING OF THE BOSTON DISPENSARY.

For the past five years the necessity of a new building for the Boston Dispensary has been discussed. Early in this year the requisite funds were secured, plans agreed upon, and in March last the active work of the charity was transferred to temporary quarters on Washington Street and the old building demolished, which had been occupied since July, 1856. The cut given below will recall the double house which so

of the institution has been restored to its old location.

The new building is situated on the site of the old building, at the corner of Ash and South Bennet Streets.

The building itself is very nearly square, the dimensions being sixty-five feet eight inches by sixty-five feet four inches, with an entrance porch and bay on Ash Street. The walls are of brick, with brown sandstone trimmings, surmounted by a slated hipped-roof, with a gable on each corner. The chimneys have been so treated as to make an attractive feature of the design, and the whole presents an appearance both original and unique, well represented by the illustration given below. The building contains a basement, first and second stories, and a commodious attic. The only finished portion in the basement is a laboratory twenty-five by forty feet, fitted up with all the requisites for the compounding of medicines, the remaining space being devoted to a store-room for the laboratory, fuel bins, and furnaces. The first story contains a hall twenty-two feet wide, which runs the entire length of the building, and which is intended as a waiting room for patients; on one side of this hall are the apothecary's quarters, with a separate staircase to the laboratory below and a special entrance from South Bennet Street, trustees' room, lavatories, and one consulting

long was known as the Central Office, and will emphasize the contrast between the old and the new. As rapidly as possible the new building has been pushed forward, and during the past week the charitable work

ing room, and the other side is divided into five consulting rooms for the attending physicians. The second story contains a hall of similar dimensions to the one below, with an ample and attractive staircase leading thereto,

with surgeons' operating, lecture, and consulting rooms, lavatories, etc., on one side, and five consulting rooms on the other. The annexed plans show the manner in which each floor is divided. The attic contains the janitor's quarters (consisting of five rooms and bath room),

and a large unfurnished apartment, which can be used for storage or such other purposes as the future interests of the institution may suggest. The building is heated by two furnaces, in addition to which each room is provided with an open fire-place, which provides

free exit for foul air. The finish throughout is ash, with floors of best hard Southern pine. Soap-stone sinks, with hot and cold water, are placed in every room, and the plumbing throughout is in accordance with the most approved sanitary rules. Each room contains a closet for the accommodation of the physician on duty, and is simply furnished with the neces-

sary chairs and tables. All the chairs throughout the house are reproductions of an old Plymouth chair, which are not only attractive by their antique appearance, but exceedingly comfortable to those who use them. The Trustees' room, which is furnished in the

Second Story. Plan.

same general style as the consulting rooms, with the addition of a simple rug upon the floor, contains the portrait by Rembrandt Peale of Benjamin Dearborn, an early benefactor of the institution.

The old picture of the Good Samaritan, which has become familiar to long generations of students from its place over the front door, and which was executed in 1797 by John Johnston, for the sum of thirty dollars, has been carefully preserved and will find an honored place within the walls. The wooden carving of the same subject, which came originally from the house of Benjamin Dearborn, and was by him given to the Dispensary by a special clause in his will, ornaments the wall of the lower waiting hall.

Any one accustomed to enter at the old door would naturally raise his eyes when passing through the new entrance to see how the old symbol of charity was perpetuated. The door is surmounted, as is well shown

in the illustration, by a bas-relief carved in Philadelphia pressed brick laid in English Portland cement. In point of construction the building is believed to be second to none in the city of Boston, great care having been taken to make it substantial and durable. The plaster work is applied directly on the brick walls, which are hollow, and the halls and rooms are well lighted by generous windows. Ash settees, designed expressly for this building, are to be provided for the halls, for waiting patients, and are to be so arranged that patients for each particular room will be seated facing and in close proximity to it.

The Boston Dispensary is the oldest charitable institution in Boston, and was the third of its kind established in America. The building which we have just described is thronged every morning with a crowd of individuals seeking relief. The enlarged space afforded at present gives ample opportunity for the growth of special departments, which have maintained an existence under some difficulties in the former restricted quarters. Clinical instruction has become quite a prominent feature in dispensary work. Comparatively few of the physicians are connected with the school, but students are for the most part welcome, and it is the policy of the management to make the opportunities here presented as widely useful as possible. The great work of the Dispensary lies in its house visiting. From 13,000 to 14,000 patients are cared for each year at their homes. This was the work originally contemplated by the founders of the charity, and it is still the silent, unostentatious, but constant ministration to the poor which only those who have watched its operations can fully appreciate. A feature, almost unique in charitable institutions, in this section of the country at least, which attracts at once the attention of those interested in the management of similar enterprises, is the matter of the distribution of drugs. For years the institution was supported by the interest of its invested funds and annual subscriptions. Little by little the number of its annual subscribers grew less and less as the earlier subscribers grew fewer, and year after year the balance sheet showed a deficit only to be made up by the sacrifice of capital or an extraordinary subscription. The principal expense by far was due to the almost unlimited distribution of drugs, and naturally, in looking for relief, it was sought by economy in this department. It was finally resolved to charge ten cents on each prescription, liberty being left each physician to distribute such free prescriptions as seemed to him absolutely necessary. The experiment was entered upon with some hesitancy, but proved from the first a success. It not only checked useless prescribing, but added a third source of income sufficient to do away entirely with the previous annual deficit, and no suffering has been entailed by the change, so far as can be seen.

SURGEON-GENERAL CRANE.

In the official announcement of the death of Surgeon-General Crane just issued, Acting Surgeon-General Huntington gives the following summary of his life:—

His record, honorable and spotless, lives after him, a source of pride and satisfaction to his friends, a model worthy of imitation by all. The larger portion of his official life was engaged in administrative duty, for which he had always manifested a peculiar fit-

ness. Selected to assist in the arduous and important duties devolving upon this Office during the latter years of the War of the Rebellion, his sound judgment, delicate sense of justice and right, deliberate action, and firm decision, soon won for him an enviable reputation, and materially assisted in raising the Medical Corps of the Army to the high degree of discipline and efficiency which has characterized it in the past and present.

In the literary and scientific work of the Office he manifested untiring interest; to his watchful care, encouragement, and aid, is largely due the successful progress and completion of undertakings which have gained for the Medical Corps the admiring recognition of the world.

Thoroughly acquainted by early experience with the requirements of his Department, assiduously attentive to the routine of business even in its details, punctilious in regard to the rights of all, and earnest in his endeavors to promote harmony and a healthy *esprit du corps*, General Crane labored patiently, faithfully, and effectively for the best interests of his charge.

In his private life he was conspicuous for his firm, devoted friendships; for his kindly interest in, and sympathy with, the joys and griefs of those about him; for his habitual attention to the courtesies which adorn life. Unselfish and generous to a fault, his many deeds of kindness and charity were done quietly and without ostentation. He needs no higher tribute to his worth as a man than the widespread sorrow which his loss has occasioned, and the respect for his memory which will long be cherished by all who knew him.

SURGEON-GENERAL MURRAY.

The promotion of Assistant Surgeon-General Robert Murray to the superior office rendered vacant by the recent death of Surgeon-General Crane fills the highest position in the Medical Service of the United States Army in a way which, we are sure, will meet with general approval. Whatever personal preferences members of the profession may have had for either of the two other prominent candidates — and each of them had many warm supporters — all will readily acknowledge that Dr. Murray by long, faithful, and eminent service has fairly earned a place whose duties, no one questions, he will discharge with entire satisfaction.

Dr. Murray, in addition to being the oldest colonel in the medical service, was in the direct line of promotion; facts which, other things being equal, should be given due weight. He played an active part in our late civil war; and both as Medical Director of the army corps commanded by General Buell, and later as Purveyor in charge of the large depot of supplies in Philadelphia, he exhibited unusual executive ability and an aggressive honesty.

Though Dr. Murray will, by the rules of the service, be retired from active service in about eighteen months, he was at the time of his appointment on duty at Governor's Island, New York Harbor, and is entirely equal to the discharge of any work which the surgeon-generalship may devolve upon him.

SPINAL INJURY AND MONEY.

DR. J. O. WHITNEY, of Pawtucket, R. I., writes us *a propos* of this subject: —

This topic has been alluded to in the JOURNAL recently. Rehoboth, another town, and a railroad entering Boston paid about \$5000 each. The three claimants are well; made rapid recoveries. A man stepped into a hole in the street in this town in June, 1882; shortly after made claim for a large sum, and was paid in a few months \$2600. I saw him in October last; told him he would, I thought, recover; recommended blisters. When he got the cash he said, "No more blisters now." His regular attendant told me, a few days ago, "The man is walking about; never had spinal inflammation; grew fat all the while." I was sure he feigned, and if his doctor is right he shammed the whole as to the palsy of the legs. A soldier injured his spine in service; a rigid bent spine, little palsy, and a large pension. A man had his cervical spine violently crushed forward; little or no palsy yet; cannot erect his head; \$2000. The late Dr. Phelps, of Attleborough, was hurt falling down stairs; palsy in hands first in a year, as I remember it; gradually got worse, and death in some ten years or more.

CAN CANCER OF THE PENIS BE ACQUIRED BY INOCULATION FROM CANCER OF THE CERVIX UTERI?

In the *New York Medical Journal* (October 27th), Dr. P. F. Mundé writes on the above subject, taking as his text the remark of a noted gynecologist that there is "undoubtedly great danger" of such inoculation insomuch that husbands should be cautioned against having coitus with wives suffering from cancer of the womb. Dr. Mundé addressed inquiries on this point to the following gentlemen: Profs. T. E. Satterthwaite, W. H. Welch, R. F. Weir, and John A. Wyeth, of New York; Vincenz Czerny, of Heidelberg; and Theodor Billroth, of Vienna, and in summing up the testimony, he says: —

"The evidence of these experts certainly does not confirm the statement that 'repeated instances of cancer of the penis being contracted in this way' (by inoculation from cancer of the uterus) 'are on record.' None have seen or known of such an instance; the reputed cases are questioned by the writers who mention them, and the general belief is that such infection by contact can occur only under the most favorable circumstances, that is, when such contact is protracted, when a predisposition to cancer exists, either local or constitutional, and when an abraded surface is present. This statement applies equally to cancer in any portion of the body. The comparatively short period of contact between the penis and the female genital organs during coition must seem scarcely sufficient for the implantation of cancer cells on an abraded spot on the penis, however fully such short contact may suffice for venereal or septic infection.

"Did such short contact of an abraded living surface with a cancerous ulcer suffice for the inoculation of that disease, surely the gynecologists — whose index-fingers cannot always be protected from slight injuries, and who, unknowingly, examine many women with cancer of the cervix, making that very diagnosis by such digital examination — would long ere this have become inoculated with it. But no such instance is recorded.

"While thus the *first authenticated, unquestionable* case of inoculation of the penis with cancer cells from

a cancerous cervix seems as yet unpublished, and while it is still doubtful whether such inoculation actually takes place, still the *possibility* of such an occurrence cannot be denied, and I trust this communication may induce gentlemen who have met with cases in point to place them on record. Certainly the subject is of sufficient interest and importance, clinically and pathologically, to merit further investigation, and, if possible, ultimate positive elucidation."

ENORMOUS MILK-FLOW.

PROF. CH. REMY, in the *Archives Générales de Médecine*, tells of a young woman, seen by him in Japan, who gave over twelve pints and a half of milk daily, and Dr. Gomez Pamo gives in the *Anales de Cirugia*, in *La Revista de Ciencias Medicas*, in Barcelona, the following, says the *Journal of the American Medical Association*: A woman, married at sixteen years of age, whose menses, established at fourteen years, continued without interruption until the first month of marriage, when she became pregnant. After delivery lactation was established, and continued for twelve months without any appearance of the menses. Becoming again pregnant, she weaned her child; and this repeated itself *fourteen* times without any complication. She nursed each of her fourteen children up to the time that she felt herself again pregnant. During her pregnancies the flow of milk diminished somewhat, but never disappeared entirely. Immediately after delivery she gave the breast to the infant. The milk was abundant and of good quality. All the children were very robust, two of them having been born prematurely. During all this time, that is, from the first month after marriage to the present, seven years after the birth of the last child, the menses have not reappeared. She weaned her last child five years since, but the flow of milk has not diminished, in spite of all treatment; it is abundant and of good quality, and the breasts have to be drawn frequently to relieve the pain caused by tension. — *Louisville Medical News*.

NOTE ON DISINFECTANTS.

DR. W. E. BUCK writes in the *British Medical Journal*: "Most practitioners must have often realized the inefficiency of disinfectants in allaying the fetor of cancerous ulcers, an annoyance which sometimes troubles patients even more than the pain or the thought of death. I have used the whole round of disinfectants for cancerous ulcers, but all have failed in allaying the fetor and keeping the ulcer clean. The disinfectants tried were carbolic acid, sanitas, terebene, resorcin, creasote, boroglyceride, chloride of zinc, charcoal, etc. After failure with these, I tried a saturated solution of hyposulphite of soda added to an equal quantity of water, and found it exceedingly efficacious. The ulcerating surface was well syringed and washed with the solution, and was then covered with rags steeped in the solution. The granulations were kept clean, and the fetor was well kept under. Most disinfectants seem to lose their virtue after a few days' application, but I have used this one for months on the same patient with continuous good effects. It is cleanly, has no smell, does not stain, and is very cheap.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM NOVEMBER 16, 1883, TO NOVEMBER 23, 1883.

MOORE, JOHN, lieutenant-colonel. Relieved from duty as Medical Director Department of the Columbia. G. O. 29, Department of the Columbia, November 8, 1883.

BACHE, DALLAS, major and surgeon. Assigned to duty at Fort Adams, R. I. Paragraph 5, S. O. 215, Department of the East, November 19, 1883.

BROOKE, JAMES, major and surgeon. Relieved from duty at Angel Island, California, and assigned to duty as post surgeon, Presidio of San Francisco, California. Paragraph 1, S. O. 162, Department of California, November 14, 1883.

HORTON, SAMUEL M., major and surgeon. Leave of absence granted October 20, 1883, extended three months. Paragraph 7, S. O. 266, A. G. O., November 20, 1883.

TOWN, F. L., major and surgeon. Until further orders, to perform the duties of Medical Director Department of the Columbia. G. O. 29, Department of the Columbia, November 8, 1883.

WILLIAMS, JOHN W., major and surgeon. Granted leave of absence for one month, on surgeon's certificate of disability, with permission to leave the limits of the Department. Paragraph 5, S. O. 157, Department of the Columbia, November 12, 1883.

APPEL, D. M., captain and assistant surgeon. Granted two month's leave of absence. S. O. 68, Division of the Atlantic, November 16, 1883.

MUNN, CURTIS E., captain and assistant surgeon. Assigned to duty at Fort Warren, Mass. Paragraph 4, S. O. 216, Department of the East, November 20, 1883.

WINNE, CHARLES K., captain and assistant surgeon. Relieved from duty at Fort Winfield Scott, California, and assigned to duty as post surgeon, Angel Island, California. Paragraph 1, S. O. 162, Department of California, November 14, 1883.

COCHRAN, J. J., first lieutenant and assistant surgeon. Assigned to duty at Fort Bayard, N. M. Paragraph 5, S. O. 236, Department of the Missouri, November 15, 1883.

RICHARD, CHARLES, first lieutenant and assistant surgeon. Relieved from duty at Fort Adams, R. I. Paragraph 3, S. O. 216, Department of the East, November 20, 1883.

WILSON, GEORGE F., first lieutenant and assistant surgeon. To report in person to Lieutenant Schwatka, 3d Cavalry, aide-camp, for temporary duty in connection with the completion of report of recent expedition to Alaska. Paragraph 3, S. O. 156, Department of the Columbia, November 9, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING NOVEMBER 24, 1883.

KENNEDY, STEPHEN D., medical inspector. Dismissed the service by sentence of a general court martial.

GYNECOLOGICAL SOCIETY OF BOSTON. — The next regular meeting of the Society will be held at the Medical Library Rooms, on the second Thursday of December, at four o'clock p. m. Remarks by H. A. Martin, M. D., on Listerism in Surgery. Post-mortem Specimen by J. G. Pinkham, M. D.

HENRY M. FIELD, M. D., Secretary.

BOOKS AND PAMPHLETS RECEIVED. — Surgical Applied Anatomy. By Frederick Treves, F. R. C. S. Illustrated with sixty-one engravings. Henry C. Lea's Son & Co.: Philadelphia.

A Manual of Psychological Medicine and Allied Nervous Diseases. Containing the Description, Etiology, Diagnosis, Pathology, and Treatment of Insanity, with Special Reference to the Clinical Features of Mental Diseases, etc. Designed for the general practitioner of medicine. By Edward C. Mann, M. D., member of the New York Medico-Legal Society, etc. With photographic plates and other illustrations. Philadelphia: P. Blakiston, Son & Co. 1883.

Influence of Constant Use of High-Heeled French Shoes upon the Female Form, etc. By S. C. Bussey, M. D. Washington, D. C. Reprint from Volume VII. Gynecological Transactions. 1883.

An Examination of Some Controverted Points of the Physiology of Voice, especially the Register of the Singing Voice and the Falsetto. By T. Wesley Mills, M. A., M. D., L. R. C. P., London, etc. Read before the American Association for the Advancement of Science, at Montreal, August, 1882. Reprint,

Original Articles.

TWO CASES OF EXCESSIVE VOMITING OF PREGNANCY, ONE FATAL.

C. ELLERY STEDMAN, M. D.

I. A. B., twenty-four years old, a married woman, native of Nova Scotia, by trade a vest-maker, was brought to the City Hospital November 22, 1882. She could give no account of herself on which dependence could be placed, and her previous condition had to be guessed at. She had the general look of one prostrated at the end of a severe fever, being much emaciated, very weak, and utterly stupid. The whole skin was dry, rough, and scaling in small pieces, making every one who saw it say "ichthyosis." The tongue was moist, and coated with a white covering at the sides, red, and inclined to dryness at the tip. Examination of the chest gave a negative result. Palpation detected an abdominal tumor, rising from the pelvis, about the size of the uterus in the fourth month of pregnancy; and vaginal examination found the cervix shortened, softened, and slightly roughened, the os somewhat patulous. Temperature, 97° F.; pulse, 98, soft and weak. Nothing beyond a trace of albumen was found in the urine. She was put upon whiskey, and given all the milk and beef tea she could be induced to take, which was very little, as she had no inclination to eat. Quinia in moderate doses was the only drug given. She began to vomit soon after entrance, and the diet was changed to milk and lime water, without much benefit. She also had marked delusions, some of which related to her children. She was, however, childless.

Five days after entrance her husband was seen, from whom the following facts were obtained: There was nothing of importance in the family history. She had had no previous illness, so far as he knew. Her married life had been pleasant, the husband had steady employment, she had no care, and was perfectly well until six weeks before admission to the hospital, when she began to be troubled with vomiting, which had occurred nearly every day since. The physicians in attendance had diagnosed the vomiting of pregnancy, and she had had no fever that he knew of. She was in her right mind until two days before entrance. She recognized her husband, but said she had not seen him for three months.

By this time the vomiting had become so persistent that everything by the mouth was omitted, and she was fed by the rectum. For a day or two there was less vomiting, but the relief was only temporary. Another vaginal examination was made, when the cervix was found red and the os more patulous. The cervix was painted with Churchill's tincture of iodine. For a day or two there was no vomiting, except when beef tea was given by the mouth by mistake. Then the enemata were rejected, and after this she was fed on champagne and milk mixed with siphon soda, of which she retained what she took. There was progressive failure from the start, and death occurred two weeks from the date of admission. The temperature remained subnormal for the first few days, and lingered about the normal line until the day before death, when it reached 100° F. The next morning, an hour or two before the end, it rose to 106.5° F. The pulse was never above 130.

¹ Read before the Obstetrical Society of Boston, February 10, 1883.

At the autopsy, by Dr. Gannett, twenty-four hours after death, the uterus was found to reach within one centimetre of the umbilicus, measuring 17.5 centimetres in its long diameter (of which the cervix occupied 1.5 centimetres), twelve centimeters transversely, and six centimetres in thickness. The vaginal mucous membrane was dark red. The cervix contained a plug of thick mucus. The wall of the uterus was about five millimetres in diameter. The decidua vera and reflexa were well marked and easily separated from each other. Between them in certain places were soft, shreddy, opaque, yellow masses, which, under the microscope, were found to be made up of fatty detritus, with many cells of nearly complete fatty degeneration. An amnion was present, containing, by estimate, half a litre of clear fluid, inclosing a foetus twenty-one centimetres in length, with a well-developed cord. The left ovary contained a corpus luteum, about one centimetre in diameter. The upper lobe of the right lung was dense, and, upon section, exhibited nodules of broncho-pneumonia, and the appearances of acute bronchitis and bronchiolitis. The heart was small. The aorta admitted only the finger, and had a thin and very elastic wall. The intercostal branches were irregularly distributed, and there were several superficial patches of degeneration in the intima. There was fatty infiltration of the liver.

When a writer with the experience of Burns makes the statement that he has "never known vomiting, purely dependent on pregnancy, end fatally;" and when a similar observation has been made by Désormeaux (Leishman), it can hardly be unnecessary to place this case on record. The autopsy showed no other cause of death than that given as the title of this paper; for the degeneration noticed in the placenta was doubtless the effect and not the cause of the vomiting and its concomitant depression, while the bronchial lesions were due to food inhaled when given in her semi-unconscious or dying condition. The painting of the os gave some relief for a day or two, and it seemed obvious to her attendant at the hospital, whose opinion was fortified by Dr. Lyman, that she was from her entrance altogether in too far advanced a state of exhaustion to permit of any operative procedure. Dr. Playfair says that he has had only once to evacuate the uterus to relieve symptoms dangerous to life from this cause. When the best methods of emptying the uterus, in the early months, for such an emergency, were inquired for in this Society at the last meeting, the questioner could elicit no reply from any who said they had much experience in the matter. It was uncertain in this case whether the patient's extreme depression was owing wholly to pregnancy, as she was unable to give any account of herself, and it was not till five days after her admission that her previous history was learned.

II. Mrs. C. D., a young woman in her second pregnancy, desired me to see her early in January. I attended her in her first confinement in January, 1881, when she had a specially easy and normal labor. She had suffered much in the early months of gestation from nausea, but not to an excessive extent. In October, 1882, she had from the 7th to the 21st trifling nausea, and the menstrual flow was more than usual. In November she was unwell from the 7th to the 12th. In December there was no flow, and nausea began on the 7th. On the 9th of January, 1883, I saw her, when she had been vomiting a great deal for some days, had

suffered from insomnia, and looked thin and haggard; still she kept down some portion of food. But after this the enemata of chloral had procured better nights, the emesis grew more persistent, till, by the 14th, when I visited her, the remedies prescribed had lost effect, and she was in an alarming condition; every particle of nutriment had been rejected for forty-eight hours; there was headache, fleeting delirium, a pinched countenance, dry brown tongue, fetid breath, constant nausea, and little sleep, immediate ejection of everything swallowed, epigastric and abdominal pain, and a rapid thready pulse. I saw that if speedy improvement did not follow, the uterus would have to be at once evacuated, before her exhaustion went too far. First, however, by means of a bivalve speculum (Higbee's) I exposed the cervix; it was flexed, very soft; the os was patulous, and very red. To this I applied liberally, with a camel's hair brush, the ethereal tincture of iodine. This caused no inconsiderable smarting; she was able to taste the medicament, and her breath smelt of it; the nausea continued through the night, and the next day, proper restrictions not having been enjoined regarding visitors, she saw several friends and talked with them at length, so that fatigue, nausea, and vomiting continued; but this disturbance being stopped, the vomiting also ceased, and since the twenty-fourth hour after the application of iodine to the os she vomited only twice, once, a week later, on account of fatigue following a troublesome enema, and once more about six days further on, when she took too rich food. On the second day after the application she was fed on milk and lime water and champagne; in a few days she drank three pints of milk daily, besides a pint of champagne, and gradually other articles of food were added as she improved. In a week she sat up, and in a fortnight after her symptoms of great danger my attendance ceased for the present.

I think that the improvement in this case may fairly be owed to the treatment adopted, and not viewed as one of the *post hoc, propter hoc* examples. In my experience considerable nausea seldom, if ever, gives way before the end of the third month, whereas this young lady had not more than completed the eighth week. She could not have gone on with the symptoms she presented on the 14th January without, in a few days, the question becoming one of life and death; and I feel that my estimation of the cause of improvement is not erroneous. I have done this little operation now four times: once uselessly, in the case reported above, and thrice in other cases, none of them so severe as Mrs. C. D.'s, and in each of these three cases the treatment was effective. It was taught me by the late Dr. E. D. Miller, of Dorchester, who said that he never knew it to be successful unless the patient complained of smarting. I do not suppose it makes much difference what form of caustic or vesicant is used, so long as the requisite impression is made on the cervix. In this case the os was abraded; in all the others, if my memory about them is good, the mucous membrane was sound. Nor can I remember that there was any displacement or flexion in any case. Of course a limited acquaintance with obstetric literature shows that Bennett and others have pointed out the benefit—many years ago—of similar treatment of the os uteri; but it does not seem to me to have been in general use. I think, however, that many women may thus be greatly relieved of troublesome vomiting when it does not promise to go on to an alarming degree, that it is safer

than other methods, particularly Copeman's, and that it is worth trying in every case of intractable vomiting.

A CASE OF TUBAL GESTATION, WITH RUPTURE AND SUDDEN DEATH.¹

BY D. D. GILBERT, M. D.

On the 18th of last month, January, 1883, there occurred in my practice a sudden death. The subject was a lady aged twenty-one years and seven months. She was of fine personal appearance, apparently of perfect physical development, and of rather brilliant mental endowment. The only noticed symptom of physical weakness had been a somewhat persistent, though slight, cough, during the last few years.

About two years ago she was married, and in May following was the subject of a procured abortion of a three months' pregnancy. The sickness connected with this was, I am told, quite severe, and reduced her strength so much that the invigorating influence of a residence at the sea-side during the warm weather was considered desirable. This was obtained at Nantasket, but the emanations there from an inland pond of stagnant water, "Green pond" so-called, I believe, prostrated both her and her husband with an attack of typhoid fever. Her sickness, during which I had the care of her, was severe and protracted, but she finally made a good recovery, and, during the last year, enjoyed what seemed perfect health, with the exception of severe abdominal cramps attending the onset of menstruation. The occurrence of these cramps dated from the miscarriage, nearly two years ago, and were said to grow more severe at each period, although she never sought professional aid for their relief. At her last menstruation, the pains were so severe, she said she did not think she could live through another such attack. This occurred November 23, 1882, and about December 23d, one month later, the cramps again attacked her, but not as severely, and did not usher in the menstrual flow. Again, about January 1st, the cramps recurred, but no menstruation followed.

She had been accustomed to use a privy in a cold out-building, and it was to this exposure that the menstrual suppression was attributed, although she, having regretted her former course, fondly hoped that the cessation of menstruation meant pregnancy. This, however, was the only thing which could be construed into a symptom of such condition. There was no morning sickness, nor was there any change noticed in the breasts. In her former pregnancy morning sickness had been present. In the forenoon of January 17th she felt as well as ever in her life, and at about two P. M. performed the act of defecation in the cold privy referred to. Immediately upon her return into the house she sank into a chair, saying "Those awful cramps are coming again and I know I cannot live through them."

The exposure to cold was again blamed as the cause, and she was helped up-stairs, put to bed, and the usual remedies resorted to. While getting up-stairs and to bed, although she did not at any time completely faint, several faint turns came over her. Relief not being obtained as usual, but the pain becoming more severe instead, I was sent for. I being unable to attend that day, Dr. C. E. Stedman kindly visited her for me. He examined her externally as well as the abdominal sore-

¹ Read before the Boston Obstetrical Society, February 10, 1883.

ness would permit, and per vaginam. He found a firm elongated cervix with closed os, and no tangible evidence of any accumulation (like hæmatocele) behind the vaginal cul-de-sac. He bade her friends cease undue anxiety, pronounced no evidences of pregnancy present, administered an opiate, and expressed the opinion that menstruation would appear and she would get relief. By midnight a slight show had made its appearance, and the patient was so much relieved as to get several hours' sleep between that time and morning when I called upon her. Upon my looking at her I was at once struck with the extreme pallor of her countenance, and when the napkin removed from her was shown to me, stained with less than one half ounce of blood, I said to her "You don't make much show for your looks; you look as though you had lost a quart of blood." I proceeded to examine the case, and could get no history of any special collapse, but rather of a persistent and severe attack of the cramps *which she had so often had, preceding and relieved by menstruation*. The thermometer showed a record of only 100.4° F; the pulse was rather weak, but not thready at 96. There had been no vomiting until some hours after morphine had been taken, and then was only occasional. The crampy pain was not as severe, but there was great tenderness complained of over the whole lower part of the abdomen; so marked was this that only the most delicate palpation was considered prudent. There was no swelling or tympanites. The patient said that although she felt somewhat relieved, yet there was a constant heavy pain in the abdomen, especially to the right and superior to the uterus, and she felt as though her bowels were swollen. Per vaginam, the uterus was prolapsed so that the os rested upon the perineum, but was not especially tender, nor did it seem to be enlarged or laterally displaced. The cervix was firm and rather long, with an ordinarily closed os. The vaginal cul-de-sacs, on either side of the cervix, were not compressed, and no swelling could be felt, by gentle examination, on either side. I was impressed by the prolapsed condition of the uterus, but as I had never made any previous examination I supposed it might be her usual condition.

I felt satisfied that there was no threatening miscarriage, and that she was not pregnant. I could get no satisfactory evidence of the tumor of hæmatocele, and was convinced that the case was one of delayed menstruation with congested ovaries. With regard to the subjective symptoms, I considered that they were hysterically exaggerated, for the temperature and pulse did not seem to agree with any serious organic lesion, and during her sickness in typhoid fever the patient had manifested marked tendency to such exaggeration, arousing the whole household on several occasions with the conviction that she was dying, and when I had been sent for being relieved simply by my assurance that there was no cause for alarm. In accordance with such an opinion I left the same comforting assurance as Dr. Stedman had done, that with patience the menstrual flow would appear, and she would be relieved.

At half-past three P. M. I was again sent for, and learned that she had been fairly comfortable since my morning visit, and had turned from side to side, but rested better upon the back. The temperature had fallen from 100.4° F. in the morning to 99.6° F., and the pulse remained about the same both as to volume and rate. No show had made its appearance, but the

crampy pains had returned. I repeated the vaginal examination, and found no apparent change. So confident did I feel that the uterus was empty that I gently introduced the sound to verify my diagnosis, and, perhaps, induce the menstrual flow. The uterus easily admitted the sound two and one half inches. Upon gentle percussion of the abdomen finding some dullness and possible fullness in the supra-pubic region, and learning that only about one ounce of water had been passed since the commencement of the attack, I thought, perhaps, a distended bladder might be the cause of the aggravated condition of affairs. I passed the catheter only to find the bladder empty and firmly contracted. I could get no satisfactory evidence of a hæmatocele, and the constitutional symptoms did not seem to warrant the supposition of abdominal hæmorrhage, for there was no collapse, and only so much vomiting as the opium taken or the ovarian congestion might account for. Once more I was forced to the conviction that it was merely one of those troublesome cases of delayed menstruation with ovarian congestion and hysterically exaggerated reflex symptoms. I then gave one sixth grain of morph. sulph. hypodermically at half-past four P. M., and waited until six o'clock, when I left the patient partially comfortable, but rather wishing for more opiate.

At half-past seven P. M., one and one half hours after I left her, and twenty-nine and one half hours after the first attack, she died, having been unconscious for one hour, and supposed to be sleeping from the opiate.

When I arrived at the house I was immediately confronted with the statement that my patient had sunk under an overdose of morphine. This seems to be the first idea that seizes upon the friends in every case of sudden death where morphine has been administered, and is a cogent reason why an autopsy should be insisted upon in all such cases. Of course I demurred at any such conclusion, as I had left my patient conscious one and a half hours after the administration of only one sixth grain of morph. sulph., and stated my belief that the cause of death had been internal hæmorrhage, comparatively slight at the first attack, and suddenly more copious within the time since I had left her, one and one half hours before her death. I said I could not tell what was the cause of the hæmorrhage, but suggested the possibility of tubal gestation and rupture. Afterwards in consultation with Dr. Stedman we decided that such was probably the case, and the autopsy so proved. I will relate the report of the autopsy later, but would now crave your indulgence for a moment. I have thus gone into the details of this case because in the opportunity afforded me of bringing it to the notice of this learned Society I seek for light in other parallel, or apparently parallel, cases. Dr. Thomas, in his work on Diseases of Women, says it is much easier in the lecture room or in the written treatise to lay down the distinction in these cases than it is to distinguish them at the bedside. So I admit that with the light afforded by the result it is quite easy to make a very probable diagnosis, but how, I would ask, in the early history of such a case could one find sufficient evidence of the real condition to justify the serious operative interference from which alone benefit could be hoped for? Dr. Thomas, in discussing the question of laparotomy for such cases, writes that of seventeen cases which he had seen, in one only had he been convinced of the diagnosis and

of the advisability of operating, and then he had been overruled on both points by a strong consultation.

Allow me to recapitulate. The only evidence of pregnancy was three weeks' delay of menstruation. Authorities state that in cases of extra-uterine gestation, "it is universally admitted that the uterus undergoes sympathetic engorgement, the cervix softens, and decidua forms." In this case the testimony of both Dr. Stedman and myself is that the cervix was long and firm. Of the formation of decidua we had no means of judging. There had been no morning sickness. It is also stated that in tubal pregnancy the rupture is generally determined by some accidental circumstance between the fourth and twelfth week, rarely later. In this case, to be sure, the onset was sudden and followed the act of defecation, in the eighth week since last menstruation, but similar attacks of intense abdominal pain had been the accustomed precursors of the menstrual flow.

The countenance is said to be deadly pale. Such was the appearance in the present case, but there was not "the thready almost imperceptible pulse" usually found in such cases, and how many of us have not witnessed a deadly pale countenance in the subjects of intense abdominal pain at the inception of menstruation. Only two days after the occurrence of this death I was called to a simple case of delayed menstruation which presented these very features.

We are also told that accompanying rupture "there is perhaps vomiting," and that "the mental faculties remain clear." Such were the conditions in our case, but how does *this* differ from what is frequently seen in dysmenorrhœa?

After rupture, a few drops of blood are said to escape from the uterus, as in this case. But, again, how frequently the same thing occurs in dysmenorrhœa, and then ceases for a while before the flow becomes established.

Playfair sums up by saying that "too often death occurs without the slightest suspicion of its cause."

Again, gentlemen, let me ask you, can you throw any light upon the means of diagnosis, and, if the diagnosis is satisfactorily made out, what is the best course to pursue, either before or after rupture?

The autopsy presented nothing unusual beyond the accidental condition, except the caseous degeneration of the bronchial glands, and the studding of the external coat of the intestines with myriads of minute miliary tubercles. Upon opening the abdomen, liquid blood was found filling all the interstices between the intestines, and the pelvic cavity was completely filled with clotted blood. The clot was found to be firmer around the right ovary and extremity of the right Fallopian tube, which was completely encased with a still firmer clot. By carefully removing this, little by little, the tumor was found in the outer third of the tube, of ovoid shape, about one and a half inches long by three fourths inch in diameter. Upon incising the tube over it, the congested villi of the chorion were beautifully exposed, and, upon opening the sac, a seven weeks' fetus was seen snugly stowed away. The point of rupture seemed to have been where the funis was attached, and where the placenta would have formed, rupture having taken place, as usual in such cases, before the formation of the placenta. The Fallopian tube was found to be impervious from the site of the cyst to the uterus. This is stated by some authorities as one of the causes of

ectopic gestation, but Playfair says it is probably induced by the abnormal gestation.

Among the causes laid down are old adhesions or bands constricting the tube. None such were found at the autopsy, but adhesion bands were found connected with the ovaries, and may have been the cause of the severe pain accompanying menstruation. As these pains dated from the miscarriage, two years previous, perhaps it is reasonable to presume that the adhesion bands were the result of the inflammation accompanying that process.

The interior of the uterus showed a marked decidua membrane, and the right ovary clearly showed the recent corpus luteum of pregnancy, thus corresponding with the tube in which the fetus was found. One case is on record where the recent corpus luteum was found in the ovary of the opposite side from the tubal pregnancy, while the corresponding ovary furnished none.

A PEDICULATED TUMOR OF THE ANTERIOR LIP OF THE CERVIX UTERI.¹

BY EDWARD T. WILLIAMS, M. D.

THE tumor here shown possesses interest only from the diagnostic peculiarities of the case in which it oc-

Diagram representing uterus with tumor attached. Side view.

Diagram representing tumor and pedicle, rear view, showing os uteri.

curred. I was called to it in consultation by Drs. O'Connell and Mecuen, of Roxbury, January 24, 1880. The patient, a woman of about thirty-five years, married, but without children, had been suffering for fourteen months with profuse menstruation and a white, at times fetid, discharge. Sexual intercourse had been regularly indulged in and was not painful, though the husband had complained of some obstacle in connection. The night before the medical consultation she had been taken with bearing-down pains, followed by the protrusion of a solid body from the vulva.

The body as I saw it was about the size of a large apple. It was red in color, and had a firm, fleshy feel. In shape it was round, somewhat knobby, insensitive to the touch, and having a smooth, mucous surface. It grew from a stalk one and a half inches in diameter, four inches in length, perfectly round and smooth, and as it seemed springing directly from the roof of the vagina. It was suggested by one of the gentlemen present that it might be an inversion, but this was negatived by its pediculated shape and the absence of any history of pregnancy. The question was, if it was a polypus, where was the *os uteri*? On the first examination no traces of the *os* could be found, the pedicle seeming to grow directly from the vaginal roof, the

¹ Read before the Norfolk District Society, January 9, 1883.

finger passing to the bottom of the *cul-de-sac* on all sides, and no *os*!

The patient being etherized and a finger inserted into the rectum, the tumor at the same time being drawn down, the body of the uterus was plainly felt in its natural position. Again, with the finger in the rectum and the hand over the pubes, the tumor being pushed up by a third party, the fundus uteri was clearly felt. A catheter in the bladder confirmed the fact still farther. This led to a more careful examination of the pedicle of the tumor, when, passing my finger carefully over its surface, I discovered on its posterior aspect about an inch from its upper end a small triangular depression, base upwards, about large enough to contain a split pea. On pushing the point of a sound into this depression I was heartily pleased to find it enter, proving it to be the *os uteri*. The sound passed upwards without obstruction to the depth of two and a quarter inches. The tumor was simply a prolongation with hypertrophy of the anterior lip of the cervix.

The diagnosis being established the treatment was clear. The pedicle was divided high up by Dr. Mecuen with the *écraseur*. There was no hæmorrhage, and examination less than a fortnight after showed nothing further than a certain thickening and slight elongation of the anterior lip.

RECENT PROGRESS IN OPHTHALMOLOGY.

BY O. F. WADSWORTH, M. D.

EYE SYMPTOMS IN SPINAL DISEASE.

IN a discussion on this subject in the Ophthalmological Society of the United Kingdom,¹ Dr. Gowers called attention to two classes of symptoms, optic nerve atrophy and intra-ocular palsies. Two general facts deserved mention at the outset. First, that these symptoms are associations and not effects of the spinal lesion. The evidence of this is, that disease of the cord of any nature may exist, in any degree, in any part, without the occurrence of these symptoms (if we except the rare paralysis of the dilators of the pupil in disease of the sympathetic tract in the cervical region of the cord); that the ocular symptoms, which may be absent when the cord disease is advanced, may exist in extreme degree when such disease is in an early stage; and that, with the exception of the sympathetic symptoms just mentioned, we know of no anatomical connection or functional mechanism by which the disease of the cord can produce the ocular symptoms. Secondly, that the ocular symptoms result from degenerative processes, and their presence shows that the cord disease is also degenerative, an indication of extreme value in cases in which acute processes mask the underlying degeneration.

Optic nerve atrophy is chiefly associated with locomotor ataxy; in other spinal diseases it is rare. As long as ataxy was believed to be a disease confined to the posterior columns of the spinal cord the concurrence of a peripheral degeneration in the optic nerve was an anomaly; but recent researches, chiefly of Pierret (confirmed in part by Déjerine), have demonstrated the frequency of degeneration in the peripheral cutaneous nerves, and its occasional occurrence in the optic centres, and our conception of the disease is thus enlarged from a mere affection of the spinal cord to a

wide sensory neurosis in which optic nerve atrophy falls into a definite place. But as the peripheral, spinal, and central optic changes cannot yet be detected during life, we must confine our clinical study to associations which can be recognized.

What proportion of cases are tabetic? or, putting the question practically, In what proportion is there neither absence of knee-jerk nor lightning pains, the two earliest symptoms? The question can only be answered by ophthalmic surgeons. If spinal symptoms are altogether absent at the time of examination we are not justified in assuming that they will occur later.

It is more difficult still to determine in what proportion of cases of tabes atrophy occurs, because the spinal and ocular symptoms tend to separate the patients. Probably the proportion does not exceed fifteen per cent. Dividing the course of tabes into three stages, (1) before affection of gait, (2) while the patient can still walk, (3) when he cannot walk except with the aid of another person, it is found that atrophy begins twice as frequently in the first stage as in the second, and very rarely in the third, and a combination of the observations of ophthalmic surgeons and of physicians would probably show the excess in the first stage to be still larger. Not only does atrophy commence, but it advances rapidly in the first stage, while the spinal symptoms often remain stationary; coming on in the later stages of the disease it often has a less progressive character.

The symptoms of the optic atrophy present more diversity than is generally admitted. While color-vision is often impaired early the field for white does not always contract before central vision fails. It may be unrestricted when there is considerable loss of acuity. The affection of sight probably varies in character just as does the impairment of sensation in the legs. Irregular defects in the fields bear upon the question of localizing the degeneration; initial temporal hemiopia has been twice observed, loss of the lower nasal quadrants once, the former suggesting that the chief lesion was at the chiasma. The occurrence of amblyopia without change in the optic disk bears upon the same question; in one case acuity was reduced to one tenth without any visible change in the disk. Rapid increase in the failure of sight is sometimes met with just as is sudden increase in the spinal symptoms. Is this attended with any variation in the appearance of the disk? Some disks are clear and excavated, others are occupied by a soft, gelatinous-looking tissue. Does any difference in course correspond with this difference in aspect? In one case with rapid failure the gray tissue in the disk was very abundant.

In other spinal diseases optic atrophy is very rare; it is occasionally seen in insular sclerosis, less frequently in lateral sclerosis, never in progressive muscular atrophy or myelitis. Probably this is due to the fact that these affect chiefly the motor, tabes the sensory, tracts. In general paralysis of the insane, which, though not strictly speaking a disease of the spinal cord, is often attended with spinal changes, atrophy is more common.

Intra-ocular paralysis comprises the second group of symptoms. Accommodation, associated contraction of the pupil, light-reflex contraction, and skin-reflex dilatation are all subserved by centres lying beneath the aqueduct of Sylvius; the path of the last is circuitous, comprehending the cervical part of the spinal cord and the cervical sympathetic. Like atrophy, the intra-ocu-

¹ Ophthalmic Review, July, 1883.

lar palsies are as common in tabes as they are rare in other diseases of the spinal cord. Loss of the light-reflex alone is most common, then total paralysis, and then palsy of accommodation without loss of the light-reflex. Among seventy-two cases of primary degenerative ataxy there was some defect of the intra-ocular muscles in sixty-six. Light-reflex alone was lost in forty-eight and impaired in seven, that is, lost in two thirds, and affected in three fourths, of the cases. In the remaining eleven cases the pupil did not contract on an effort at accommodation, and in most of these accommodation was also lost. The percentage of cases representing intra-ocular palsies was, in the first stage of tabes, eighty-four; in the second ninety-three; in the third one hundred. Thus the symptoms usually begin early, but there is a manifest tendency for the cases which escape at first to suffer later on. As a rule there is no correspondence between the pupil symptoms (size, inequality, or irregularity) and the spinal symptoms, but in one case of tabes the pupil was smaller on one side, and on this there was unilateral sweating of head and face, probably from sympathetic paralysis. The reflex dilatation on stimulation of the skin (to the loss of which when the light-reflex is lost Erb has called attention) cannot with all care be invariably obtained in persons beyond middle age. Though usually lost with the light-reflex it sometimes persists, especially when the pupils are large.

Intra-ocular palsies are excessively rare in other diseases of the spinal cord, with the exception of general paralysis of the insane. The instances of this disease which come among hospital out-patients present slighter mental changes and a less progressive course than the asylum cases. In them the impairment of the intra-ocular muscles (usually loss of the light-reflex) is almost as frequent as in tabes, being present in two thirds of the cases. Intra-ocular palsies may occur without spinal disease, and are often preceded by constitutional syphilis, as Mr. Hutchinson has shown in the case of ophthalmoplegia interna. Of fifteen such cases there was a history of constitutional syphilis in seven, — a fact of considerable interest in connection with the frequency of the symptom in tabes and the disputed relation of syphilis to the latter disease. The pupil symptoms are doubtless in these cases due to a degenerative process, but we are as little justified in denying as we should be in affirming their relation to syphilis.

Dr. Hughlings-Jackson dwelt on the variety and complexity of symptoms in tabes dorsalis — joint affections, gastric crises, several very different affections of the eyes, bladder symptoms, etc. Of the so-called typical symptoms one or more may be absent; ataxy is often absent; with ataxy the knee-jerks may be present. In one case of seventeen years' duration the Argyll-Robertson symptom was not found. Some of the so-called typical symptoms occur in other diseases. The commonest pupil symptom occurs in some cases of general paresis. Knee-jerk is absent in many morbid conditions, for example, diphtherial paralysis, a disease which, superficially regarded, has sometimes a great likeness to locomotor ataxy. There are degrees of some, at least, of the symptoms; thus, no ataxy, degrees of ataxy, and, so to speak, a degree beyond ataxy, an inability to walk at all. If there are not degrees of pupillary conditions there are various such conditions. The width of the symptomatology is exceedingly different in different cases. There may be

the Argyll-Robertson phenomenon with no other definite nervous symptoms, and when so the nature of the case, beyond, perhaps, the vague diagnosis of nerve degeneration, cannot be determined. A case of tabes without ataxy may present a far wider symptomatology than one with ataxy.

Though eye symptoms are common with disease of the cord, they are unknown with lesion of the cord except when it occurs in the cilio-spinal region, as, for example, in a section of half the cord from a stab with a knife (contraction of pupil on the same side and narrowing of the ocular aperture).

The Argyll-Robertson pupil is found not only when sight is slightly impaired, but also when there is only bare perception of light; in one case he found it when the loss of sight was absolute. The pupils enlarge when the patient "makes believe" to look at the clouds, and contract when he "makes believe" to look at his fingers held near him. On the other hand, with considerable impairment of sight the pupils may remain contractile to light. He mentioned cases to illustrate the varying width of association of optic atrophy with other tabetic symptoms.

Cases were cited of double optic neuritis with absent knee-jerks. In one of these there was tumor of the left cerebral hemisphere, but no morbid changes were discovered in the spinal cord. He had seen double optic neuritis with absent knee-jerks, and no, or at any rate no other, localizing symptom.

He had said that diphtherial paralysis was owing to a morbid affection of the sympathetic system; he ought to have said that the ocular, the palatal, and the rarer circulatory symptoms (great slowness of pulse) are morbid affections of parts supplied through ganglia of the sympathetic; he believed the spinal cord, as well as higher parts of the nervous system, to be morbidly affected in this disease. He had not seen a case of so-called diphtherial amaurosis in a stage where the paralysis of the ciliary muscle was complete.

He also cited cases illustrating the various intra-ocular palsies met with in tabes.

Mr. Bevan Lewis, from systematic examination of a large number of cases of general paralysis of the insane, was led to the conclusion that ocular symptoms occurred in the majority. The sequence of morbid phenomena occurring in the iris in this disease appeared to be this: That there is, first of all, loss of reflex dilatation to cutaneous stimulation; next, the action to light is lost; and in the final stage, paralysis of both iris and ciliary muscle is developed, and becomes in the end complete.

Dr. Savage believed that the examination of the optic disk would increase our knowledge of general paralysis of the insane. In recent years he had come to appreciate certain changes occurring in the disks, not of all, but of a considerable number of patients suffering from general paralysis. In one class tabetic symptoms were prominent, and sometimes preceded the other symptoms by many years; in these cases changes in the disk were common; he had, however, only recently learned that these changes were not confined to the patients who presented tabetic symptoms, but that they occurred also in those who presented symptoms of lateral sclerosis. The question arose whether this lateral sclerosis was secondary to degeneration of the motor tracts in the brain. It was now generally recognized that "general paralysis" is a wide term, embracing a number of separable conditions; in

making this subdivision, a careful attention to alterations in the optic disks and in the reflex phenomena would be of great assistance.

Dr. Sharkey narrated three cases of atrophy of the optic disks with symptoms of disseminated sclerosis. In one of these there had been previously optic neuritis.

Mr. Nettleship said that there were clinical reasons for believing that optic nerve changes in locomotor ataxy begin at the disk, not in the trunk of the nerve or optic tract; he had seen no unequivocal cases of spinal disease, in which sight failed before ophthalmoscopic changes became apparent, whilst it was commonly observed, on the other hand, that the appearances of atrophy are more pronounced than the condition of the sight would lead us to expect. Of seventy-two patients under his care with progressive atrophy of the optic nerves, thirty-six were undoubtedly tabetic, eight had symptoms of mixed spinal and cerebral disease (allied to general paralysis), seven had some other forms of chronic spinal disease, not ataxy, eight had, besides optic atrophy, reflex irido-plegia ("spinal pupils"), but no other symptoms of disease of cord or brain; in the remaining thirteen there was no proof of disease of the nervous system, but in some of these the notes were incomplete. He had been struck with the rarity of the complete absence of spinal symptoms in progressive atrophy. Alluding to the mode of failure of vision in progressive atrophy, he pointed out that the field of vision is often invaded in a precisely symmetrical manner in the two eyes, although at any given time one eye is usually worse than the other. He had only seen two or three cases in which one eye became quite blind before the other began to fail.

Dr. Gowers, in closing, said the knee-jerk was very seldom absent in health. He had formerly recorded a few cases, but he had not since met with a single instance, and was, therefore, inclined to doubt the accuracy of his earlier observations. In testing the pupil for the light-reaction there were several fallacies to be guarded against. If artificial light were used, it was especially necessary to see that the patient did not accommodate for the source of light. It was necessary to remember that in disseminated sclerosis sight might be lost, owing to a patch of sclerosis in the optic nerve, without any primary atrophy of the disk.

UNILATERAL RETINITIS ALBUMINURA IN A PATIENT WITH BUT ONE KIDNEY.

Yver¹ reports the following rare case in a Spaniard, aged forty-three, who had had most of the subjective and objective symptoms of parenchymatous nephritis, and in whom the right eye remained absolutely intact throughout the entire course of the disease. In the left eye there were the usual yellowish-white masses of exudation in the retina, beneath the vessels in the region of the macula, and between the latter and the disk. There were numerous punctate hæmorrhages, and some larger extravasations. Vision was not much affected when the patient first came under observation, but subsequently was almost entirely lost. After he had been under treatment about six weeks, the vision improved almost to the normal standard, and there was a considerable diminution of the retinal exudation. He subsequently, however, grew very much worse, the vision was again nearly lost, and the patient died in

about ten weeks from the time he first came under observation. At the autopsy the right kidney was found to be entirely absent, there being not a trace of kidney, artery, vein, or ureter, though the suprarenal capsule was present in its accustomed place, and was of normal size. The place ordinarily filled by the kidney was occupied by a portion of the right lobe of the liver, enormously hypertrophied. The left kidney was in its normal position, was considerably hypertrophied, and presented the characteristics of the large, white, parenchymatous nephritis.

PERIODICAL RECURRENT PARALYSIS OF THE MOTOR OCULI.

Hasner² describes the case of a girl of seventeen years, who, since her thirteenth year, with each recurrence of the catamenia, suffered from paralysis of the oculo-motor nerve of the left eye. The affection began with headache and vomiting. While the paralysis lasted the eye was slightly prominent and deviated outward and a little downward. It could be moved inward as far as the median line, but only with secondary deviation outward of the right eye. By the second day headache and vomiting had ceased, and the paralysis of the levator of the lid was already less. The third day, when the menstrual flow stopped, the movements of both lid and eye became again free, though there was still slight secondary deviation of the right eye, and mydriasis persisted. The mydriasis, indeed, did not wholly disappear at the end of a week.

Hasner thinks it probable that here, accompanying menstruation, there is vaso-motor irritation in the region of the fissure of Sylvius and the pedunculus, which causes periodically pressure paralysis of the nucleus of origin, of the root district, of the left motor oculi, with reflex action on the vagus. Hence, periodically, muscular energy is much diminished, but returns immediately when the circulation again becomes normal. The combination of the symptoms suggests that the hyperæmia is greatest at the anterior end of the nucleus, spreads from there toward its posterior parts, and recedes in the reverse direction. There is the possibility that if the phenomena recur for a long time a permanent paralysis of the motor oculi may result either through inflammatory process or from the gradual development of a tumor.

Reports of Societies.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. W. SWAN, M. D., SECRETARY.

FEBRUARY 10, 1883.

A FATAL CASE OF TUBAL PREGNANCY, WITH OBSCURE DIAGNOSTIC SYMPTOMS. AUTOPSY.

DR. D. D. GILBERT, of Dorchester, read the case.³

DR. LYMAN said that the interesting point in the case reported was as to diagnosis between rupture caused by tubal pregnancy and hæmatocele. From the history in this case he did not see why the diagnosis of hæmatocele was not the natural inference. In fact, it was a case of hæmatocele originating in a rupture of the foetal sac. The only case of tubal preg-

¹ Recueil d'Ophthalmologie. March, 1883. N. Y. Medical Journal, July 14, 1883.

² Prager med. Wochenschrift, November 10, 1883.

³ See page 580 of this number of the JOURNAL.

nancy which had occurred in his own practice exhibited the same symptoms, but in a more exaggerated form, with an antecedent history which left no doubt of the correct diagnosis. The rupture took place at about the sixth week of recognized pregnancy; there were sudden hæmorrhage, with violent pain, and an immediate tendency to collapse, and these symptoms following a jump from her bed to the floor. Dr. Lyman asked Dr. Gilbert if he supposed that the rupture took place at the time of the earlier pains.

DR. GILBERT replied that there were no indications of rupture at the time of the earlier pains. His theory was that the hæmorrhage was slight at first, but that it began with the last of the abdominal cramps.

DR. HOMANS contrasted the case of Dr. Lyman with that of Dr. Gilbert, and said that in the report of the latter he could see nothing on which to found a diagnosis of tubal pregnancy.

DR. E. G. CUTLER stated, in answer to a question by Dr. Lyman, that he had never seen a case of tubal pregnancy in which a uterine decidua membrane had not been formed.

On motion of DR. BROWN it was voted that the thanks of the Society be presented to Dr. Gilbert for his interesting paper, and that a copy be requested for publication with the records of the Society.

THE "LONGINGS" OF PREGNANCY.

DR. FORSTER remarked that he was surprised to find that Lusk, in his *Midwifery*, observes: "The consuming desire for unwonted articles of food, which is customarily termed 'longings,' I have never yet witnessed, and am tempted to regard as, in a measure, mythical." He therefore reported the case of Mrs. T., who had an uncontrollable desire for uncooked starch. Mrs. T., thirty-eight years of age, was married when fifteen years of age, and fifteen months later gave birth to her first child. She has since been delivered of six living children, and had two miscarriages. When about three months pregnant with her sixth child, who was born November, 1867, she commenced to eat dry corn starch, at first only in small quantities, but at the time of confinement she was using four one pound packages a week. After delivery she gave up corn starch for common starch, the use of which she continues to the present time. The daily amount varies, the better she is the more she eats. Her general health has been fair, and has not suffered from any intestinal disturbance excepting slight irregularity of the bowels.

DR. WILLIS, of Waltham, mentioned the case of a pregnant woman who ate writing paper.

TWO CASES [ONE FATAL] OF EXCESSIVE VOMITING IN PREGNANCY.

DR. C. ELLERY STEDMAN read the cases.¹

DR. J. STEDMAN stated that he had tried the method of painting the cervix with tincture of iodine with good result in three cases of this condition, and with partial relief in several other cases.

DR. FORSTER remarked that after a case of placenta prævia (which he would report later in full) he had been obliged to inject subcutaneously ergot, brandy, and quinine in different places, and that now over a month had elapsed, and the ulcers caused by the ergot and brandy had but just healed, while that caused by the quinine was quiescent until about a week ago, when the eschar fell, leaving an excavated ulcer about

one half an inch in depth, which is slowly healing under disinfecting washes and iodoform.

DR. C. ELLERY STEDMAN remarked that it was his custom to inject all irritant solutions vertically and deep into the flesh in order to avoid inflammations and abscess.

DR. TOWNSEND, of Natick, said that on a hot day in June, three years ago, he was called to assist in the delivery of a woman with a figure-of-eight pelvis. Many attempts had been already made, and the patient was apparently moribund. He performed craniotomy, and effected delivery, and during the process two gentlemen plied the patient continually with hypodermic injections, consuming in this way the enormous amounts of *not less than* —

Whiskey	3 vi.
Ether sulphuric	3 i.
Camphor	℥vi.
Ergot fluid extract	3 ss.

The syringe was introduced as soon as pulse flagged. In four days less than a year afterwards the patient was again confined at term, and Dr. Townsend was again sent for to assist. Meanwhile an arm had come down, and Dr. Townsend turned and easily delivered the patient of a living child.

DR. HOMANS alluded to the case of a patient who went into collapse after confinement. Morphine, brandy, and tincture of digitalis were freely and repeatedly administered hypodermically, and the patient recovered, without abscesses. The injections were made just beneath the skin.

DR. RICHARDSON observed that Dr. Townsend's case was interesting, as showing the great advantage of doing version in preference to attempting to deliver with forceps in the case of a figure-of-eight pelvis.

DR. WILLIS, of Waltham, remarked that the shock that he had observed in cases of placenta prævia was greater than one would expect from the loss of blood or other circumstance. He had seen fatal instances when these could hardly account for the result.

DR. C. E. STEDMAN had seen fatal cases in which the hæmorrhage had been well under control and everything had gone on well as regards the process of delivery, etc.; a result which in one case at least was probably due to pulmonary embolism.

ANATOMICAL SPECIMEN. RETAINED PLACENTA.

DR. HOSMER exhibited the specimen, and gave the following account of the case: —

The only point of interest attaching to the specimen was the fact that a placental mass was retained nearly ten weeks after a premature birth which occurred about the middle of a second pregnancy, and was then expelled in a state of perfect preservation and without any putrefactive change.

FETAL CALF WITH A FIFTH LIMB GROWING FROM ITS BACK.

DR. HOSMER exhibited the specimen.

DR. W. F. WHITNEY's description of the specimen is as follows: —

It was about eight to ten inches in length, and apparently somewhat macerated. From the lower part of the dorsal region was apparently a fifth leg, poorly developed, and without any large amount of bony material. The hoof was represented by three parts instead of two, and from this it was suggested that the leg was possibly double. From the condition of the specimen

¹ See page 529.

this could not be determined. Otherwise the animal appeared well formed. Internal organs not examined.

A SELF-RETAINING SIMS' SPECULUM.

DR. FORSTER exhibited to the Society a self-retaining Sims' speculum invented by Dr. Hunter, of New York, and described in a recent number of the *New York Medical Record*, which he had recently obtained, and had answered in his practice every requirement, and dispensed entirely with the necessity of an assistant.

DR. BOARDMAN had also used the speculum at his clinic at the City Hospital.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

CHARLES H. WILLIAMS, M. D., SECRETARY.

OCTOBER 1, 1883.

DR. J. B. SWIFT reported

TWO OBSTETRIC CASES ACCOMPANIED BY UNUSUAL SYMPTOMS.

On December 15, 1882, was asked by Mrs. M. to attend her in her thirteenth confinement, which she expected in about three weeks. Her other twelve children were alive, and she had no history of miscarriage. Her last child was born five years ago. She was forty-four years of age, and was very much surprised to find herself pregnant, which she would not acknowledge until she was fully seven months along, attributing the cessation of the menses, the only symptom of pregnancy perceived by herself, to her age.

She said her general health was good, the only thing she could complain of was being tired, she having worked hard about the house during the last month or two.

The symptoms which she mentioned, and which she said always came on in her former pregnancies two weeks before labor, were slight pains in her abdomen similar to the first pains of labor, only not so severe. No examination was made at this visit. A few days later she sent for me again, saying that the pains had increased in severity, and came on at a regular time each day, about four P. M., and would last through the evening well into the night. The pains were situated in front, running down into the groins and thighs, and were especially severe on the right side, feeling as if the child were pushing hard against the womb on that side. The digestion was good and the bowels were regular, though she did not have much appetite. There was no other sign of labor, and except for the pains keeping her awake some nights, she expressed herself as being very comfortable. This condition of things continued until January 10, 1883, when the pains lasted all day, and were so severe that she could not stand. On my visit I found her in bed suffering intensely. The pains came on at regular intervals, and the uterus could be felt contracting through the abdominal walls. On external examination the child could be mapped out, the back being to the front on the left side. By the vagina the cervix was not taken up, but was very soft; the external os was open, admitting the finger readily, the internal os closed. The pains had no effect on the cervix. The head was presenting high up. She was given one

fourth of a grain of morphia sulphate by the mouth and one drachm of compound liquorice powder was ordered to be taken at night, for although she insisted that her bowels were in good condition, I thought there must be something there causing the trouble.

The next day she said the morphia had relieved the pain, but had made her sick, and she had vomited. The powder had not operated. I advised her to remain in bed, and, as she was not taking enough nourishment as it seemed to me, prescribed a tablespoonful of extract of malt in a glass of sherry three times a day. From this time she improved, and the pains did not trouble her very much until the night of January 21st, when they were again quite severe. On examination at this time I found the cervix soft, considerably shortened since the last examination, the os open, but there was no indication of labor. I asked her how she would know when she really was in labor, and she replied she did not know, as the pains all along were exactly like the first labor pains.

At two A. M., January 24th, I was summoned by her husband, who said that our patient was suddenly taken with expulsive pains, and the child was born before he could get out of the house. On my arrival I found the child in the bed, still attached to the placenta, which had not been born. I tied and cut the cord, and removed the placenta, which was in the vagina. The uterus was well contracted, and there was no hæmorrhage. One drachm of the fluid extract of ergot was given. The child was a male, weighing seven pounds.

About half an hour after the birth of the placenta the patient complained of a pain in the uterus, and was seized with a violent chill which lasted ten minutes, finally yielding to stimulants internally and hot bottles placed in the bed. The chill was so severe that the whole bed shook, the patient's teeth chattered, and her face became cyanosed. During the chill the uterus was firmly contracted, and seemed to be held as if by a spasm. It remained firmly contracted after the chill. The temperature was normal, the pulse 70, and the patient very comfortable.

She was seen again at ten A. M., and found to be improving. Had taken a breakfast of gruel; had no after-pains, and was feeling very well. There was very little lochial discharge, the napkin scarcely being stained, and this was the only time that there was any red color to the discharge, which itself lasted only a few days. The milk appeared in the breasts forty-eight hours after delivery, and the convalescence progressed without an unfavorable symptom, she refusing to stay in bed after the seventh day.

The points of interest to me in the case were: the false pains coming on so long before labor set in, and the absence of the lochial discharge.

Most of the books to which I have had access speak of the occurrence of false pains, and dismiss the subject in a few sentences, saying that "pains simulating labor pains may come on a short time before labor sets in, that they are generally due to some digestive disturbance, and are usually remedied by opening the bowels."

In this case they seemed to me to be due to some other cause, but I was unable to find any, unless they could be attributed to the general condition of the woman.

The almost complete absence of the lochial discharge was an unusual occurrence, and I could find nothing about it in the books, though I have seen a few similar cases reported in some of the journals, and in the

American Journal of Obstetrics for July of this year. Dr. Tausky, in a paper read before the Academy of Medicine of New York, entitled *How to Secure the Best Possible Physical Condition after Parturition*, says: "A little hæmorrhage after parturition is very dangerous, and should be arrested. The accoucheur should be regarded as guilty of malpractice who would permit a slight quantity of blood to escape from the genital organs of a woman for days after parturition. Not a single drop of blood should appear after the completion of the third stage of labor; the napkins when removed should be perfectly free from color; and should they be colored, the physician should at once institute an examination with reference to the source from whence the blood came, and set about arresting it."

That this is not the usual experience was shown in the discussion which followed.

My second case presents quite a contrast with the first.

February 2, 1883, eleven P. M., I was asked to see a patient who was supposed to be having a miscarriage. On my arrival at the house I found a young girl about twenty years old, who thought she was six months pregnant with an illegitimate child. She could not tell when her last menstruation occurred, as she was never regular. She had been "keeping company" with a young man for some time, and did not know that she was pregnant until four weeks ago, when she was examined by two physicians, whom she had consulted on account of frequent micturition, and who told her that she was about six months advanced in pregnancy. So far as she could tell she had been perfectly well during the past year. Had had no nausea nor any illness whatever until lately, when she had been troubled with the frequent desire to urinate.

During the day she had been troubled, as she had been told that her lover was about to marry another girl, and to this anxiety she attributed the threatened miscarriage. After going to bed she noticed that she was passing water involuntarily. There was no pain, but all through the evening she had had attacks of shivering, which she says are due to her being so nervous. There is no sensation of cold accompanying these attacks. An external examination showed the uterus reaching above the umbilicus, and the breech of the child was felt at the fundus. The child was readily outlined lying on the right side of the abdomen. The foetal heart was heard to the right of the median line a little below the level of the umbilicus, 150 a minute.

Internal examination. The vagina is moist and cool, the pelvis roomy; the cervix entirely obliterated, and the os dilated to the size of a silver dollar. The head is felt through the membranes, with very little liquor amnii intervening. Water coming away from the uterus in considerable quantity, especially during contractions of the uterus, which take place during the shivering attacks. The girl is quiet and calm, except when the shivering comes on. These attacks continued at regular intervals, and with each attack the uterus could be felt to harden, and the membranes would become tense. There was no pain whatever.

At two A. M. (February 3d) the os was fully dilated, and the head engaged in the brim O. R. P. At this time she complained of some pain in the back, the head began to descend. The pains soon be-

came the regular expulsive pains of a normal labor, the head descended, rotated, and at 3.25 A. M. a perfectly formed female child weighing six and a half pounds was born. The placenta soon followed, and there was no further trouble.

At my visit the next morning the nurse called my attention to the woman's breasts, which were perfectly flat, with nipples more resembling a man's than a woman's. The third day after delivery the breasts began to enlarge, and by night were as large as the average woman's, but the baby could not nurse on account of the nipples, nor could it draw any milk through a nipple shield. I tried to relieve the breasts with a breast pump, but could not get any milk to run. As the breasts were very hard and heavy, causing considerable pain, I had the nurse rub them, which softened them considerably, but no milk came. They were then supported by a bandage and left alone. I ordered the bowels to be opened each day by an enema.

The next day the breasts were still full and rather painful, but from this time they gradually softened and grew smaller until they were perfectly flat again. The woman made a rapid convalescence without an untoward symptom.

Painless labor is spoken of in the books, but is considered of rare occurrence. Cases are seen where the first symptom of labor is the commencement of the expulsive stage, but in our case we had the first stage well marked except the pains, and these were replaced by chills. Women frequently complain of chilly sensations toward the end of the first stage, but I can find no mention of these sensations lasting through this time as we had here.

The breasts were evidently undeveloped, the nipples being merely rudimentary. That there was glandular tissue in the breasts I think is shown by the fact of their filling up and presenting the nodular feel which we get in the normal breast, but the ducts were not open, for no milk would flow from the nipple. The question arises whether the ducts might not have been opened by shaving off the nipple and the skin covering the small alveola, but I did not feel justified in attempting it.

DR. REYNOLDS said that it was very uncommon to have such absence of lochial discharge as in the first case reported. In the first stage of labor one may often have only chills without much pain, and where the delivery comes with a single expulsive effort it is often difficult to be sure that no previous pains have occurred.

In answer to a question, if the pains could have been due to rheumatism of the uterus, the reader thought not, as there was no rise of temperature as mentioned by Cazeau.

DR. C. M. GREEN had seen cases where pains simulating labor pains had occurred hours or days before delivery, often ceasing when labor began. They were attributed to rheumatism, and usually came in laboring women; he had had two cases where the lochia ceased on the second and third day, respectively, in each case twenty minim doses of ergot with a small amount of opium were given three times a day, but in most cases he would not give it. Dr. Matthews Duncan proposed giving ergot in cases of involution, but he thought that the use of ergot in such cases was unnecessary, and might act badly by contracting the vessels and hindering their proper action.

DR. SHERMAN stated that at the Lying-in Hospital

the routine practice is to give small doses of ergot for two weeks after delivery. He had not noticed any marked diminution in the amount of the lochial discharge.

DR. O. F. WADSWORTH then read a paper on

SOME CASES OF HYSTERICAL AFFECTION OF VISION.¹

DR. HASKET DERBY mentioned a case of a lawyer who had used a fan and umbrella to protect the eyes from the light for more than a year, but on making a journey to England was able to give up both.

He also spoke of a case where a lady became suddenly blind in one eye. The history was good, and the patient in comfortable circumstances. She was willing to undergo any treatment which might help her to regain her sight; the pupil reacted well to light and the fundus was normal. On putting a prism before the sound eye, after having told her that it would make her see double, she did see two objects, and then covering the well eye she became convinced of the fact that she was also seeing with the blind eye; and having had this fact proved to her she had no further trouble.

DR. EDES said that hysterical blindness often comes with hysterical hemianæsthesia with loss of hearing and taste. A theory of local anæmia has been suggested.

DR. WADSWORTH had examined several such cases, but had never been able to find any diminished fullness of the retinal vessels.

DR. DENNY said that Professor Schweigger² reports a case which resembles in general outline the cases just read, which he also regards as hysteric disturbance of vision. Hysteria, it should be remembered, is specially characterized, however, by its multiplicity of symptoms, and the case reported was that in which no other symptom of hysteria appeared than sudden loss of vision in the right eye of a girl of fourteen, nor was there any evidence of simulation. She was told that hypodermic injections of strychnia would relieve her, while pure water only was so used; in three weeks she recovered normal sight.

Dr. Landesberg³ reports a case of similar character, where simulation was not manifested, and gives to it the name of blindness due to imagination (*Vorstellungsblindheit*), but not that of hysteric affection of the vision. Thus he placed before the eyes of a patient who believed she was blind in one eye an arrangement of lenses whereby she seemed to see an object with the blind eye while really seeing it with the sound eye alone. The blindness thereupon was immediately transferred to the sound eye, and she saw plainly with the other eye.

Among the eighty cases of hysteria in the male sex collated by Dr. Klein⁴ I find but two definite examples of disturbance of vision, while all the cases were characterized by a *multiplicity* of symptoms besides, such as convulsions, globus, crying, laughing, hemianæsthesia, etc. One of these was a case of reflex amaurosis, and the other one of dyschromatopsia with limitation of the field of vision.

Malarial cachexia, anæmia, and general weakness will cause a temporary disorder of vision, which may be relieved by quinine, iron, change of location, etc., as is well known. I have encountered such cases in the form of night-blindness among soldiers in malarial

swamps, and in the form of transitory hemiopia due to weakness, anæmia, and cachexia without hysteria.

Two cases of what is usually called hysteric amaurosis, dyschromatopsia, and achromatopsia occurred during my service at the City Hospital in women, also under the care of Dr. Edes, that were marked by a great variety of symptoms, and in neither was there evidence of simulation. Among the symptoms, which were well defined, and of few days' duration only, were hemilateral amaurosis, hemianæsthesia, hemihyperæsthesia, hemiparesis, loss of hearing in one ear, and anæsthesia of the middle ear and tympanum, loss of taste on one side of the tongue, loss of smell in one nostril, transfer of sensation from the anæsthetic side to the other by sinapisms or electricity, hemianæsthesia of fauces and mucous membranes, polyuria, ischuria, hæmaturia, and hæmatemesis. To obtain still other positive signs which should exclude simulation I gave subcutaneous injections of pilocarpine, and found hemilateral sweating as a result in each case. The temperature by the thermometer was one half degree lower in the axilla of the hemianæsthetic side, while the arterial tension, as determined both by the finger and the sphygmograph, was markedly lower at the wrist of the anæsthetic side than upon the other radial.

Darting movements made with sharp instruments toward the pupil of the blind eye—the other being closed—produced no involuntary closure of lids or movements, while, when the other eye was opened, winking, scowling, and drawing back instantly followed such experiments. In neither case was there any local disease of the arteries or heart. These cases, while illustrating the multiplicity of symptoms which are usually associated with so-called hysteric disturbance of vision, might be designated better as neuroses of the sympathetic nervous system or functional disorders of the vasomotor nervous system.

REPORT OF THE EXECUTIVE BOARD OF THE MASSACHUSETTS MEDICO-LEGAL SOCIETY ON THE WORK OF THE MEDICAL EXAMINERS FOR THE YEAR 1882.

THE report of the Executive Board for the year ending December 31, 1882, is herewith presented. In its general features this report does not differ from the reports of previous years. Thirty-eight members of the Society have sent in summaries of their work for the year. From these the following statistics are derived:—

Whole number of views.....	954
Number of views followed by autopsies.....	189
Number of autopsies refused by authorities.....	1
Number of inquests held on above.....	179
Inquests at which medical examiners testified....	79
Cases reported by medical examiners as probably resulting from violence, in which no inquest was held.....	23
Number of deaths from natural causes.....	336
Number of deaths from railroad accidents.....	133
Number of deaths from other accidents.....	241
Number of deaths from suicide.....	117
Number of deaths from criminal violence.....	64
Number of deaths directly or indirectly the result of intemperance.....	128
Prosecutions resulting.....	17
Convictions in cases now finished.....	7

Two of the convictions resulted from cases begun in the previous year. The total number of convictions

¹ Reported in the JOURNAL for October 18th.

² Schmidt's Jahrbücher, No. 5, 1882.

³ Ibid.

⁴ De l'Hystérie chez l'Homme. Paris, 1880.

reported would seem to show a very meagre result from such a large amount of viewing and dissecting. It is probable, however, that many cases, like the two given above, are carried over into succeeding years, and do not appear at all in the reports, which in this respect, therefore, do not adequately represent the practical result of our work.

The relative proportion of autopsies and inquests to views for the period of five and a half years is as follows:—

Years.	1877 Six m.	1878	1879	1880	1881	1882
Views.....	448	82	770	935	945	954
Autopsies.....	116	196	182	182	179	189
Ratio of autopsies to views.....	26%	28%	28%	24%	19%	20%
Inquests.....	99	172	151	197	189	179
Ratio of inquests to views.....	22%	20%	20%	21%	20%	19%

The following percentages show the relative frequency of the various causes of death for the same period:—

Years.	1877	1878	1879	1880	1881	1882
Natural causes.....	24%	40%	38%	35%	40%	38%
Railroad accidents.....	18	14	11	14	18	15
Other accidents.....	80	26	29	28	28	27
Suicide.....	16	11	15	12	12	13
Violence.....	12	9	7	11	7	7
	100	100	100	100	100	100

Reports of individual cases to the number of one hundred and sixty-three have been made. The causes of death have been given in tabular form in two hundred and seven other cases. From the three hundred and seventy cases thus reported the following tables have been compiled:—

CAUSES OF DEATH IN GROUPS.

	No.	Percentage.
Accidental.....	186	37%
Natural.....	160	43
Suicide.....	51	14
Violence.....	26	6

ACCIDENTAL CAUSES OF DEATH.

Railroad casualties.....	55
Drowning.....	31
Falls.....	18
Run over by wagon.....	9
Poisoning.....	5
Chloral.....	3
Aconite.....	1
Methylic Alcohol.....	1
Falling bodies.....	3
Explosions.....	3
Machinery accidents.....	2
Blasting accidents.....	2
Suffocation.....	1
Caving of gravel bank.....	1
Shooting.....	1
Kicked by horse.....	1
Hæmorrhage (bite of tongue in fit).....	1
Exposure.....	1
Burning.....	1
Over-exertion in jumping rope.....	1

NATURAL CAUSES OF DEATH.

Heart disease.....	46
Stillbirth.....	19

Premature birth.....	16
Alcoholism.....	15
Apoplexy.....	14
Unknown.....	11
Pneumonia.....	8
Peritonitis.....	6
Bronchitis.....	4
Pulmonary hæmorrhage.....	3
Meningitis.....	3
Old age.....	2
Congestion of brain.....	2
Aneurism.....	1
Cholera infantum.....	1
Cirrhosis of liver.....	1
Diarrhœa.....	1
Delirium tremens.....	1
Typhoid fever.....	1
Phthisis.....	1
Debility and exposure.....	1
Septicæmia.....	1
Marasmus.....	1
Poisoning (?) (habitual use of morphia).....	1

DEATHS BY SUICIDE.

Drowning.....	10
Hanging.....	10
Cutting throat.....	6
Shooting.....	16
Poisoning.....	8
Arsenic.....	2
Opium.....	2
Illuminating gas.....	2
Strychnine.....	1
Chloral.....	1
Cutting arm.....	1

DEATHS BY CRIMINAL VIOLENCE.

Infanticide.....	11
Suffocation.....	1
Neglect to tie funia.....	1
Neglect in general.....	2
Exposure.....	2
Strangulation.....	1
Blow on head.....	1
Drowning.....	1
Unknown method.....	2
Abortion.....	3
Blows.....	2
Pistol-shot wound of abdomen.....	1
Stabs (wounding carotid artery).....	1
Incised wounds of neck.....	1
Incised wounds of vulva.....	1
Privation.....	1
Blows, kicks, or violent pressure on abdomen.....	2

The great falling off in the number of full reports of cases is very noticeable. The attempt of the Society to obtain and preserve in its archives complete records of all cases coming under the notice of its members has not proved a conspicuous success. Many of the reports thus far obtained are interesting and valuable; but a portion of them are so meagre in their details as to be practically worthless. It is obvious that the standard of the Society in this particular was set too high, and that the burden placed upon members by the requirements of the by-laws is greater than many of them are willing to bear. Two members of the Society report upwards of one third the total number of cases. The amount of simple clerical work, to say nothing of brain labor, involved in preparing complete histories of all these views and autopsies, is something fearful to contemplate: while for those who have fifty or even thirty cases the task is no easy one if conscientiously and thoroughly performed. It is therefore thought best by the Executive Board to advise that members be allowed to report their cases in tabular form, using blanks provided by the Society with headings like the following:—

- (1.) Number of view.
- (2.) Location of view.
- (3.) Date of view.
- (4.) Name of person viewed.
- (5.) Age of person viewed.
- (6.) Sex of person viewed.
- (7.) Supposed date of death.
- (8.) Cause of death in form of medico-legal diagnosis.
- (9.) Autopsy.
- (10.) Inquest.
- (11.) Verdict.
- (12.) Prosecution.
- (13.) Conviction.
- (14.) Remarks.

By making use of paper with fine rulings, and devoting several lines to each case, enough space will be obtained to state all the leading facts,—all certainly that are employed in preparing our annual reports. Every member is supposed to keep a careful record of all his cases; and if any have the time and feel willing to prepare copies of these records for the benefit of the Society, the Corresponding Secretary should stand ready hereafter, as in the past, to receive and file away in the usual manner all such reports. It is possible that medical examiners who are not members of the society may, if appealed to, fill out the above mentioned blank forms, and that with a little extra effort we may be able to obtain complete statistics for the whole State. The object to be attained is so desirable that it certainly seems worth our while to make the trial.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

C. B. NANCREE, M. D., RECORDER.

THURSDAY evening, November 8, 1888. The President, DR. TYSON, in the chair.

CYLINDRICAL-CELLED EPITHELIOMA OF CÆCUM.

Exhibited by DR. WILLIAM E. HUGHES.

Thomas C., white, aged forty-six. Occupation of late years car-driver, before that laborer. Always exposed much to weather, but had led a fairly regular life, using stimulants, tea, coffee, and tobacco very moderately. Much family and business trouble, about which he had worried a great deal. A brother and his father's sister have phthisis. With these exceptions the family history is good. There is no instance of the occurrence of a malignant growth. Married, and the father of five healthy children. He had had the ordinary diseases of childhood. When quite young he received a severe injury leading to ankylosis of the left knee and consequent wasting of that extremity. In boyhood he had intermittent fever. When a young man any indiscretion in diet or exposure to exhausting influences would produce a slight diarrhoea, never lasting long, and always easily controlled. With these exceptions he was perfectly well and strong, and this tendency to looseness of the bowels seemed to be overcome as he grew older. Seven years before coming under observation he had, following exposure, an attack of diarrhoea, lasting a few days and disappearing spontaneously. In the next month his bowels were regular, but at the end of that period the diarrhoea recurred. For the next four years he had diarrhoea alternating with regularity of bowels, the diarrhoea becoming more violent and uncontrollable and the periods of regularity shorter. For three years the diarrhoea had been constant, worse in the winter, and much aggravated by exposure, overwork, or any other indiscretion. There

had been no pain in the abdomen, and only rarely a slight feeling of discomfort, due, as he thought, to flatulence. Appetite, till within a year, had been good; since then capricious, with occasional slight dyspeptic symptoms. During the three years in which the diarrhoea was constant he slowly and steadily lost flesh and strength, though his general health was good. During the last twenty months the quantity of urine passed exceeded the normal, at times rising, according to the patient's statement, to more than a gallon in twenty-four hours; this exceedingly profuse urination being always accompanied by extreme thirst. During the latter part of this period there had been œdema of the lower extremities, much more marked on the left, appearing and disappearing irregularly. When he came under observation the patient presented the following conditions: Tall, emaciated, his frame gave evidence of great muscular development at one time. Expression moody, discontented. Complexion sallow, earthy, pasty. Sclera pearly. Appetite poor; very slight dyspepsia. Tongue clean. Bowels are moved from ten to fifteen times in twenty-four hours. The movements are neither preceded nor accompanied by pain. The passages are dark, watery, frothy, and exceedingly fetid. They contain neither blood nor mucus, though the patient says if he takes cold large quantities of mucus invariably make their appearance in the stools. Abdomen slightly tympanitic; not the slightest tenderness can be developed on the deepest pressure, nor can any abnormality be detected. However, a thorough examination could not be made, as the ribs extended almost to the crests of the ilia. The apex beat of the heart is in the fifth interspace just outside of the nipple, the impulse strong, heaving, and the second sound somewhat accentuated. The quantity of urine passed is increased to specific gravity 1012, and it contains neither albumen nor tube casts, though the patient says large quantities of albumen were found in it some weeks before. Slight œdema of lower extremities, more marked on left; no fluid in any of the cavities. He was under treatment a week; improving markedly, the number of stools being reduced to two per diem. At the end of that time he was seized with a chill followed by fever (102° F.) and intense exhaustion. He died in a few hours, apparently from general failure of vital forces.

Autopsy (ten hours after death). Some serous fluid in each pleural cavity, with old adhesions at apices. Lungs showed puckerings and cicatrices at apices. Both were extremely œdematous, with decidedly hypostatic congestion. Heart somewhat hypertrophied. Mitral valve slightly thickened but competent. Left ventricle firmly contracted. Right less firm, its cavity containing currant jelly clot and small amount of chicken fat clot. Liver somewhat cirrhotic and fatty, size normal. Kidneys showed thickening of walls of arteries and adherent capsules. Small intestine normal. Wall of the large intestine thickened, the thickening due principally to a hyperplasia of the mucous membrane, which was soft, velvety, dark lead-colored, studded with hard white points, the hypertrophied follicles. In the cæcum, completely surrounding the gut but producing no obstruction, was a ragged, ulcerated neoplasm, developed apparently from the mucous membrane. It was abruptly limited by the ileo-cæcal valve, and did not involve the vermiform appendix. The abdominal lymphatic glands were all enlarged. There were no secondary deposits in any of the organs. Microscopic exam-

ination of the growth showed it to be a cylindrical-celled epithelioma.

Remarks. The case was one in which evidently the neoplasm was the result of the chronic catarrhal condition of the mucous membrane of the large intestine, or else the cancerous growth had been of unusually long duration (seven years). That the former was not the case is probable from the fact that the catarrh was limited to the mucous membrane below the ulcerated growth, and was apparently due to the irritating discharge, the small intestine being perfectly healthy. Sudden death is quite common in chronic diarrhoea, especially the form due to cancer, and is very difficult of explanation. Possibly some sudden disturbance of the vaso-motor centres, the cause acting through the abdominal sympathetic, may be at the bottom of it.

CASE OF SARCOMA OCCUPYING THE ANTERIOR MEDIASTINUM.

By DR. EDWARD T. BRUEN.

A. M., a male, came under my notice as a patient in Blockley Hospital in December, 1882. His family history was excellent, and he had enjoyed good health until eight months before. His illness had been chiefly characterized by emaciation and pain in the chest. He was a tall, slightly-built man, and when I saw him had evidently lost half his weight. The pain was most severe over the upper segment of the sternum, and radiated around the chest. There was dullness on percussion over the upper piece of the sternum; the respiratory murmur at the right border of the upper part of the sternum was bronchial. The cardiac sounds, particularly the second sounds, were almost absent. The noticeable feature about the above signs of percussion and auscultation seemed to be the localization of the pathological physical signs to a district scarcely more than four square inches at the upper part of the sternum; the dullness downwards was continuous with the cardiac dullness. Elsewhere the physical signs were normal. There was, in addition to the above, some lividity of the face, with enlargement of the veins of the upper part of the neck. The patient died on February, 1883, from exhaustion, worn out by the pain, which increased with the progress of the case. The case was conspicuous by the absence of any symptoms implicating other parts of the body.

Post-mortem Examination. On removing the sternum and the cartilages they were found adherent upon the right side to a mass which occupied the anterior mediastinum. The growth was seven inches long measuring from the sternal notch, terminating in a somewhat diffused thickening of the visceral pleura, covering the anterior margin of the upper and middle lobe of the right lung. The growth was distinctly sausage shaped, and about two and a half inches broad. It overlay the aorta, pulmonary artery, and the vessels of the neck, thereby compressing them and accounting for the muffling of the second sound during life. The growth seemed to be unconnected with the anterior mediastinal glands; the glands at the root of the lung were only slightly swollen, but not generally affected. The calibre of the trachea was not diminished. The glands of the neck were not affected on either side. Laterally at the lower portion of the growth the pleura of the lung was thickened at the line of contact, but the lungs were free from traces of disease. The pericardial tissues at the right side of the chest were also somewhat thickened. The growth it-

self was of fibrous consistence, of a gray white color, and contained a softened tissue running through its centre.

It was found on microscopic examination to be composed of medium-sized lymphoid cells, mixed with spindle-shaped cells and imbedded in a homogeneous stroma, or a stroma which consisted of reticulated fibrous and wavy fibrous tissue. The peripheral thickening of the pleura and pericardium were made up from similar elements. In conclusion, let me say that during life the tumor was diagnosed, and the opinion entertained, that the growth would prove a sarcoma, and not a cancer. This diagnosis was based upon the location of the disease in the anterior, instead of the posterior, mediastinum, upon the age of the patient, and upon the rapidity of the progress of the case, which began in April and terminated in the following February. There was also entire freedom from inherited tendencies to morbid growth, but it was noted that the patient had been a shoemaker, and when at his work was accustomed to press some of his tools of trade against the sternum. The second interesting point was the absence of any tendency to excite morbid formation in the adjacent tissues. The growth apparently originated in the connective tissues of the mediastinum and not in the bronchial or thymus glands, and I believe that I am justified from microscopic examination in considering the growth a form of sarcoma, and as being of special interest to the Society on account of its rarity. Without having made an extensive examination of recorded cases, yet in looking over the Transactions of London Pathological Society the past ten years I find only three cases recorded of sarcoma of the anterior mediastinum, and in only one of these was the growth as localized as the one I present this evening; in the others the glands of axillæ or neck were involved, and also in one of them the tissues of the lungs.

DR. FORMAD then exhibited the apparatus used by Koch in the cultivation of bacteria, and described the methods used.

DRS. RIDGE, of Camden, and SHAKESPEARE, of Philadelphia, discussed the subject.

A MEETING OF REPRESENTATIVES OF STATE BOARDS OF HEALTH AT DETROIT, NOVEMBER, 1883.

REPORTED BY THE SECRETARY, J. N. MCCORMACK, M. D.

CONCERTED ACTION BY STATE BOARDS OF HEALTH.

THERE has been a growing conviction among leading sanitarians intrusted with the official execution of practical health measures that while the work of the American Public Health Association is of inestimable value in promoting the interests of sanitary science and sanitary reform, there is a constantly increasing need for an annual conference of State and other health officials in regard to practical affairs of their every-day work, some part of which work cannot profitably be discussed in a public meeting consisting largely of persons not familiar with its details.

After due consideration a meeting of representatives of State Boards was held at Detroit during the recent meeting of the American Public Health Association, at which, after discussion, it was decided to call a meeting of the secretaries or other representatives of all State Boards of Health in Washington during May,

1884, for the purposes mentioned, and with the view of organizing a section devoted to State Board work in the present Association or the formation of a permanent separate organization especially adapted to the needs of State Boards of Health. Drs. Henry B. Baker, of Michigan, and J. N. McCormack, of Kentucky, were appointed a committee to confer with and secure the coöperation of all the State Boards in fulfilling the object of the meeting, and Drs. C. W. Chamberlain, of Connecticut, J. E. Reeves, of West Virginia, and Stephen Smith, of New York, were appointed a committee on organization to report at the meeting in May. The American Medical Association meets in Washington in May, and another reason for holding the meeting in Washington is that the representatives of the State Boards may also have an opportunity for conferring with the senators and representatives in Congress from their respective States in regard to national sanitary legislation. It would seem that whenever the health authorities of all the States shall meet, discuss, and agree upon the course they will pursue with respect to yellow fever, cholera, small-pox or any disease which endangers public health without regard to State lines or borders, and whenever all State Boards shall act in concert, considerable progress will have been made in solving the problem of what are the best methods for national action in regard to inter-State and maritime quarantine or inspection and disinfection as well as in the practical control of epidemic diseases within the several States of this country.

Recent Literature.

Insanity. Its Classification, Diagnosis, and Treatment. A Manual for Students and Practitioners of Medicine. By E. C. SPITZKA, M. D. New York: Birmingham & Co. 1883.

Since the trial of Guiteau, either as a direct result or owing to accident, the study of psychological medicine has had new life infused into it. This fact is demonstrated in part by the large number of papers, books, and articles of every sort that have appeared in print from time to time. The book before us is one of the larger kind that have gone to swell the stream. The present year has already seen three good-sized treatises on insanity by American writers, and as six weeks still remain, we may see one or two more. This fertility in authorship is, however, only commendable, as it is a duty of every medical man to share any special knowledge with his less fortunate brethren. In past years we have been too much in the habit of keeping our experience or our new ideas pent up within our bosoms, and if at last the infection not of German measles but German verbosity and love of *Zeitschriften* and *Jahrbuchs* has reached us, we may hope to see the standard of American medical literature much elevated.

Dr. Spitzka possesses the true German love of scientific studies and facility of putting them on paper. Judging from the way his books read, he is a perfect Niagara both of ideas and words, and when the English language becomes a little contracted, he easily expands it to suit his purposes. But this manual of only 400 pages is merely an introduction to a larger work on insanity to appear in a few years. For this reason almost all bibliographical references are omitted, we

are told. This we regard as unfortunate, as many of us may be dead and buried, or in too reduced circumstances to buy the larger work when it appears, and we like a book compiled in a manner that will be useful for immediate study.

As this manual is no "more than a surface view of the domain of insanity," it is hardly fair to subject it to too extended criticism.

The author endeavors like many others to formulate a satisfactory definition of insanity, but we find it both cumbersome and lacking in clearness. We are rather sorry that he did not follow the example of the most recent German writers he speaks of, and not give any definition at all. Insanity is a disease which cannot be accurately described in a few words, and the sooner we recognize this fact the better.

Neither are we satisfied with the definition of delusions, hallucinations, etc. Delusions, for instance, are called "faulty ideas growing out of a perversion or weakening of the logical apparatus." "Logical apparatus" has no meaning either from a scientific or grammatical point of view. "Faulty ideas" are not false ideas, and not of necessity delusions. And any "faulty" idea (we use the word *faulty* under protest) must grow out of some perversion of our reasoning powers.

The chapter on The Delusions of the Insane, though brief, is clear and interesting, and the following one on Imperative Conceptions and Morbid Propensities may be commended for saying a good deal in a few words.

Of special interest is the chapter on The Morbid Anatomy of Insanity. The importance of functional changes is clearly pointed out, and the rarity of coarse formative changes in most of the primary psychoses is especially noticed. Many of the extraordinary pathological findings of some investigators Dr. Spitzka shows to be accidental or natural. The views expressed throughout the chapter are conservative and in accordance with the highest principle of scientific investigation, which accepts no half-truth, but proven facts alone.

The system of classification is not above criticism, as Dr. Spitzka himself says, but we have never as yet seen a perfect classification.

Taken as a whole the book is a valuable one, and of real use to the alienist. Its chief fault lies in its indulgence in personalities, which are a blot to any textbook. Some of its minor faults have been already mentioned. Its chief merit consists in its effort to present the subject in a clear, accurate, and scientific manner.

State Charities Aid Association, No. 82. Handbook for Hospitals. New York: G. P. Putnam's Sons. 1883.

Hospitals, Infirmaries, and Dispensaries: Their Construction, Interior Arrangement, and Management. With Descriptions of Existing Institutions, and Seventy-four Illustrations. By F. OPPERT, M. D., M. R. C. P. L. Second [English] Edition, Revised and Enlarged. London: J. & A. Churchill. 1883.

The first of these books was prepared in 1877 for the use of those members of the State Charities Aid Association whose duty it is to visit the public hospitals in New York County and other counties of that State. It is addressed chiefly to women visitors, and enters into many domestic details of hospital manage-

ment, such as cleanliness, order, tone of discipline, nursing, diet, and laundry work; hospital house-keeping, in short, in the inspection of which judicious and intelligent women may be of the greatest service. This book should be in the hands of every one, male or female, connected with a hospital, whether in a resident or visiting capacity. It is well arranged, concise, handy, and for the most part practical and thorough.

Dr. Oppert's work is an octavo volume of a more ambitious character. It was originally written in German, in which language it has been through two editions, as well as a previous one in English. Its scope has now been enlarged, and it is divided into a first part of eighty-four pages on the construction, external and internal, administration, and subdivision of hospitals; and a second part, of nearly two hundred pages, devoted to a description, with numerous diagrams, of "all the most noteworthy hospital establishments in existence." For an account of English, French, and German hospitals the book does very well, but its value beyond that may easily be estimated when we remark that the Johns Hopkins Hospital is dismissed in half a dozen lines; one page is given to the hospitals of Massachusetts, of which the Boston City Hospital takes up two thirds, no mention being made of the General Hospital; only two pages are given to New York, the New York Hospital is not mentioned; Philadelphia receives four lines, the Pennsylvania Hospital not being noticed, etc., etc.

Dr. Oppert's book is a pretentious and phenomenally imperfect *parvum in multo*. Should it ever reach another edition, he should either attempt less, or offer more. This is, we are aware, strange advice to be tendered to a German.

Recherches Cliniques et Therapeutiques sur l'Epilepsie, l'Hystérie, et l'Idiotie. Compte rendu du Service des Épileptiques et des Enfants, Idiots, et Arriérés de Bicêtre pendant l'Année 1881. BOURNEVILLE, Physician to Bicêtre. E. BONNAIRE et WUILLAMIS, Internes. Paris: A. Delahaye et E. Lecrosnier. 1882. Pages xvi, 178.

This is one of the series issued as Publications du Progrès Medical. The sixteen pages contain a brief report of the more important events and patients for the year, a table of deaths, with the causes, and a table of the patients remaining at the close of the year. The rest of the book is devoted to detailed and carefully prepared histories of the more interesting cases, giving many autopsies, with illustrations of the abnormal brains. Cases of idiocy from various causes, observations of epilepsy, a case of hystero-epilepsy in a boy, and the effect produced upon epilepsy by measles, are among the more interesting subjects considered.

The boy affected with hystero-epilepsy was thirteen years old, of a neurotic family; he had numerous convulsive attacks; there were numerous tender hysterogenous points along the sides of the spine, and in the fifth and seventh intercostal space, over the sternum, on the sides, and nearly in the centre of the iliac fossae. The treatment consisted first in tonics, capsules of bromide of camphor, baths, and gymnastic exercises; then, when it was possible, cold douches in spray and in jet, at first thirty seconds, then forty.

There was an epidemic of measles among the epileptics. The attacks of epilepsy were markedly diminished

uring the measles, but on recovery therefrom the epilepsy retook its previous severity.

A Guide to American Medical Students in Europe. By HENRY HUN, M. D. New York: William Wood & Co. 1883.

This book fills a need long felt, and should be in the hands of every medical man going abroad. Before starting for Europe the student has always a thousand questions to ask, and before arriving there the answers to most of them have been forgotten. With this guide-book at hand many of these questions can be answered at the right moment and much time saved. The introduction on the technique of travel, mode of living, study of German, etc., though short, is to the point. The advice, for example, to spend a few months in a German family studying the language to the neglect of medicine is excellent. The plan of living during term time in lodgings and eating at restaurants while popular perhaps with most students is extremely distasteful to many, while living in a German *Pension*, with all its drawbacks, offers attractions and advantages to which the author seems hardly to have done justice. The courses of study in the Universities of Austria, Germany, Switzerland, Paris, London, and Dublin are thoroughly and excellently described, a compilation made with great care, and conveying information gained hitherto only from scattered sources. The schedule of a student's day in Vienna contains nine courses on different subjects between eight A. M. and eight P. M., leading one to wonder where the *studying* comes in, and how much of what is seen and heard in those twelve hours is carried away for future reference. The advice to go to Prague or Dresden to study midwifery, to Heidelberg to study pathological anatomy, to Leipzig to study anatomy, etc., is quite refreshing after the description of work at Vienna, and leads one to suspect that a student with two years or more at his disposal might best at first pursue a few studies at a time in some of the smaller German universities, and finish up his stay by using his eyes and ears for a time at Vienna. Each person must, however, settle these questions according to his individual needs and opportunities, and to all this effort of Dr. Hun will furnish a valuable guide and book of reference. One improvement suggesting itself is an alphabetical index, through which, for example, one could ascertain easily the whereabouts of the various professors whose names are prominent in medical literature.

Gout in its Protean Aspects. By J. MILNER FOTHERGILL, M. D. Detroit: George S. Davis. 1883.

We suppose this is to be regarded as Part II. of one work of which Indigestion and Biliousness, published in 1881, was Part I. Dr. Fothergill is an easy writer and a good book maker. The dedication is to Dr. Garrod, and those who wish to read rather than to consult will find this a handy book in an agreeable style, though it will not dispossess Dr. Garrod's treatise of the space upon their shelves.

—The late Dr. Samuel E. Fitz bequeathed two thirds of his residuary estate to Harvard College for the use of the Medical School.

Medical and Surgical Journal.

THURSDAY, DECEMBER 6, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

INTERCOLLEGIATE FOOT-BALL.

THE Committee on Athletics of Harvard College recently issued by Prof. Charles Eliot Norton, its chairman, a formal prohibition of the game of foot-ball as at present played among the students, to take effect immediately. The grounds on which the decision was made are thus expressed:—

"The attention of the Committee on Athletics has been sharply called during the past few weeks by the numerous accidents which have happened at foot-ball on the playgrounds of various colleges, to the conditions under which the intercollegiate match games of foot-ball are now played, and to the rules of the American Intercollegiate Association for the season of 1883. Some of these rules seem to the committee to be highly objectionable. Rules 19, 28, and 38, a copy of which I append, appear to allow of no other inference than that the manly spirit of fair play is not expected to govern the conduct of all players, but that, on the contrary, the spirit of sharpers and of roughs has to be guarded against. The committee believe that the games hotly played under these rules have already begun to degenerate from a manly if rough sport into brutal and dangerous contests. They regard this as a serious misfortune in the interest of the game, which, if played in a gentlemanly spirit, may be one of the most useful college sports as a means of physical development. They regret that they did not give earlier attention to the character of these rules, and thus earlier come to the conclusion which they have now reached, namely, that the Harvard eleven cannot be allowed to take part in any further intercollegiate match games until substantial changes in the rules have been made."

The rules objected to read as follows:—

Rule 19 — The referee shall take out time for unnecessary delay. Shall decide disputed points, and shall disqualify any player whom he has warned twice for intentional off-side play, intentional tackling in touch, or intentional violating of rule 28.

Rule 28 — No hacking, throttling, butting, tripping up, tackling below the hips, or striking with closed fist shall be allowed.

Rule 38 — No player shall intentionally lay hands upon or interfere with an opponent unless he has the ball.

The members of the eleven at once took measures to change the rules which were objected to, and it is

understood that the amendments made have been approved by the Committee of the Faculty, and the restriction will be taken off. A summary interdiction of the game in the midst of the season is liable to work an apparent injustice to those, especially members of other colleges, who have arranged for games to be played on certain fixed dates, as such prohibition may debar them from receipts of gate money which has been counted upon to meet current expenses. But on the other hand it has been said, we know not how truly, that several of the members of the Harvard Team are more or less seriously incapacitated by reason of injuries received in the game, and that it has become necessary to draw upon some of the substitutes to fill the places of the disabled, while but few of the original players have not suffered to some extent from the roughness of the game.

We have ourselves been present at an intercollegiate foot-ball match, where all the players were supposed to be gentlemen, which at times strongly resembled a free fight, and we should have had no difficulty in picking out the original offender on that occasion. The unavoidable risks of foot-ball played by the Rugby rules are sufficient, as is quite frequently illustrated in the English papers, without adding any further hostile embellishments, such as slugging.

We are glad to see that the Harvard Faculty are appreciating their responsibility for the physical welfare, in these respects, of the young men placed under their charge. As is well known to many of our readers, the whole subject of athletics has been referred to a committee with almost full powers, on the ground that the questions constantly occurring as to specific details may meet with a more prompt and intelligent decision than could be obtained from the larger body. But a more specific direction still is needed, which can only be secured by intrusting the supervision of this important matter to some one man, who by personal experience of the requirements of athletic games, and at the same time a knowledge of the laws of health, and some maturity of judgment, will be able to exercise a wise and temperate control. We understand that such a plan is in fact contemplated, it being under advisement to appoint a man, preferably a graduate and perhaps one connected with some of the professional schools, to such a position, the rank and compensation of which shall be equal to those of an instructor in the college. If this plan is pursued and a suitable incumbent for the new office secured, there need be no unfortunate interruption, to the disappointment of other collegiate teams, of games already appointed, while there will be security for our young men against the various unnecessary perils of athletic contests. The appointment of a medical director of the gymnasium was a step in the right direction, but the good offices of that official are shared by all the students, while the field of the new officer would be a narrower one, though still very important for the class who participate actively in athletic sports. With the hearty coöperation which should exist between the medical director of physical culture and the not necessarily medical man who superintends the domain of athletic

contests, there should be a maximum of all the good effects of strength-developing sports, and a minimum of the overtraining and overstraining that have been the bane of such contests.

ANNUAL REPORT OF THE SURGEON-GENERAL UNITED STATES ARMY, 1883.

THE annual report prepared by the late Surgeon-General Crane is submitted without his signature by Acting Surgeon-General Huntington. It contains the usual account of the finances and transactions of the office. The figures giving the comparative tables of disease and mortality between white and colored troops are very interesting, but the numbers for a single year are hardly large enough to be very valuable. The average number constantly on sick report during the year was among the white troops at the rate of thirty-eight per thousand, among the colored troops thirty per thousand.

It is interesting to note that the colored troops make a particularly favorable showing in the small number of admissions for alcoholism and its results, exhibiting as they do a rate of only four per thousand, in marked contrast to a rate of seventy-six per thousand of mean strength among the whites. On the other hand, in diseases of the nervous system they have an unexplained preponderance.

Among the causes of death, diseases of the respiratory organs occupy the first place. Extremes of temperature are supposed to account for this in part, but natural causes are not considered as the only factor; to a larger extent insufficient ventilation of barracks and dormitories, as well as irregular and unequal distribution of artificial heat during cold weather, must be held responsible."

Wounds, injuries, and accidents stand second on the list of causes impairing the effectiveness of the army. The large number recorded in this class may probably be attributed to the use of troops in mechanical and laborious employments, which form so large a proportion of the soldier's duties. As an indication of the peculiar hardships to which our troops are exposed, the rates of admission for wounds, accidents, and injuries are 122 per thousand higher than those reported for the German army, and 142 per thousand higher than the decennial rate of the British army.

An interesting account of a mild epidemic of yellow fever at Fort Brown, Texas, is given. Including soldiers and civilians there were sixty-eight cases and six deaths.

Measures for preventing the spread of the disease appear to have been promptly enforced; isolation of the sick and a thorough police and disinfection of the post was tried, but, unfortunately, without success. Abandonment of the infected locality on the twenty-third day of the epidemic was followed by better results, as only three cases are reported in the camp, which was pitched a few miles from the fort, and as these occurred within three days after the move the men may be considered to have been infected before

their departure. The removal of a portion of the command from the northern to the southern part of the garrison appears to have materially checked the progress of the disease, and a subsequent move of the same troops on the forty-third day of the epidemic to camp, from which, as in the former instance, only three new cases were sent back to the fort, practically brought it to a close.

The details of the amount of work done in the Record and Pension Department show that great pains are taken to preserve the invaluable documents which relate to the War of the Rebellion. It seems scandalous that with all our surplus revenues these papers, the loss of which would add unsurmountable difficulties to the adjustment of claims still pending against the government, should be left without adequate protection against fire. The means have been devised, however, for the rescue of the more important volumes. In Section B (in hired buildings on F Street) nearly six thousand hospital registers and death and discharge registers have been placed on the ground floor, in truck cases, so arranged that in the event of danger they can be run out of the building into the street; in Section A (in the building on Tenth Street) similar precautions have been taken for the rescue of three thousand additional registers. If sufficient warning can be given the greater part of such records as are indispensable to the pension work of the Office will probably be saved.

The manuscript of Volume V. of the Index Catalogue is reported as in an advanced stage of preparation, and the first part of it is now going to press. An estimate for Volume VI. has been prepared, and it is hoped that the necessary appropriation will be promptly granted.

A manuscript catalogue of the Army Medical Museum is now in course of preparation, which will include a description of all specimens in the Museum at the present time. As such a catalogue is indispensable to the practical usefulness of so valuable a collection, it is hoped that authority may be granted by Congress for the printing and binding of this work also. The present catalogue was printed in 1866, and contains a description of less than one third of the present specimens.

As physicians we have special reason to be proud of the Army Medical Department.

THE REPORT OF THE UNITED STATES MARINE HOSPITAL SERVICE.

THE Surgeon-General of the Marine Hospital Service of the United States has presented his annual report for the year ending June 30, 1883. During this year 40,195 patients received relief from the Service, of whom 13,356 were treated in the hospitals, and 26,839 at the dispensaries; 327,312 days' relief were furnished. The receipts from all sources were \$426,620.35, and the expenditures \$469,966.21. This includes \$35,440.92 which was expended on account of extraordinary alterations and repairs to hospital build-

inga, which may be looked on as a permanent investment. In addition to medical supplies furnished to the Marine Hospital Service in general the vessels of the Revenue Cutter Service have also been largely supplied from the purveying division of the Service.

Of nineteen candidates out of thirty-seven applications who presented themselves for examination for admission to the medical staff five were passed.

The examination of pilots for color-blindness has been continued through the year, and no complaint is now made about the examination. It has become apparent that the examination should be conducted not only for color-blindness, but for acuteness of vision and hearing as well. Persons have applied for positions as pilots who were able to see but a very short distance, and some blind in one eye, and accounts have appeared in the public press of pilots who were discovered to be almost entirely deaf.

The recommendations previously made by the Surgeon-General concerning the physical examination of seamen as preliminary to shipment, and the establishment of a national snug harbor for seamen injured or disabled in the line of duty, are renewed. He calls attention to the need of competent medical service for patients of the Merchant Marine in Alaska, and the general subject of medical relief for Indians and others.

The experience of the United States since the passage of the Act of April 29, 1878, has abundantly demonstrated that a reasonable national quarantine system is a necessity; not the old-fashioned forty-day affair, nor yet such a quarantine as would in any measure interfere with or cripple the local quarantine establishments, but one that would efficiently supplement them. The appropriation made by the government during the past two years has been principally used at the Southern and South Atlantic sea-board in the maintenance of national quarantines and the quarantine at Pensacola in aid of the local Board of Health, and it may probably be fairly claimed for the Service that the non-introduction of yellow fever into the cities of the Gulf coast during the last season is at least partially due to the maintenance by it of such quarantines, and the hearty coöperation of the local Boards of Health. A valuable report on the yellow fever epidemic of 1882 in the United States and Mexico, including full statements by officers of the Service, affords ample proof of the efficacy of quarantine in this disease. The duty of excluding yellow fever and similar infectious diseases at the point where they naturally make their appearance, namely, on the sea-board, can be very properly discharged by the Marine Hospital Service. With this limit the duty of the government apparently ends; the question of local municipal sanitation is one which may with propriety be left to the States. The entire expenses on account of the epidemic appropriation for the two years, up to June 30, 1883, was \$54,678.10.

The usual tables of statistics, papers on selected cases from hospital practice, and reports of autopsies follow.

MEDICAL NOTES.

— Dr. E. M. Snow, for so many years Superintendent of Health and City Registrar of Providence, R. I., has not been chosen to those offices for the coming year.

— "A gentleman and a slugger!" was the titular form in which the salutation of an enthusiastic admirer found expression at a recent reception given to our distinguished fellow-townsmen, Mr. John L. Sullivan, who, however, is not a member of any collegiate foot-ball team.

— Foot-ball as played in England is not without its dangers, as the following attests: "At the Oxford University foot-ball matches on Saturday several serious accidents occurred. Mr. Gore received serious injuries, but is progressing favorably. Fowler, of Magdalen, sustained a fracture of one of his legs. At Cambridge, in the Rugby match between University and Kensington, Colbourn Hope broke his leg, and another Cantab was very much hurt. One of the Kensington men had his nose smashed, and another severely sprained his ankle. Most of the players received slight injuries, and minor casualties occurred in other games." But we are assured by a young gentleman, lately from Oxford, that he had never seen "slugging" until present at the last Harvard-Yale Freshman Match. It is not essential even to the Rugby game.

— The death is announced of Louise Lateau, the Belgian girl whose manifestations of the "stigmata" gave her a world-wide reputation some years ago. It will be remembered that the results of the most careful examination of the Academy of Science were the detection of fraud and imposition, which had escaped previous observers.

NEW YORK.

— At the quarterly meeting of the State Board of Health, held at Albany, November 21st, Dr. Smith, Health Officer of the port of New York, reported a diminution in the cases of small-pox arriving at the port, and attributed this in part to his efforts during the past year to induce greater interest in the subject of vaccination on the other side of the Atlantic. He suggested the advisability of a conference of the quarantine authorities of the various States, with a view to uniformity of procedure in matters of disinfection, and called special attention to the dangers arising from the importation of rags. Mr. James F. Gardiner made a report from the Committee on Drainage, Sewerage, and Topography, and Dr. Elisha Harris, the secretary of the Board, presented a statement of the progress of the work of investigating the outbreak of diphtheria at the Batavia Blind Asylum. The public nuisances maintained by the large starch factory at Glen Cove, Long Island, were made the subject of a special report to the Governor, in which a number of recommendations for the abatement of the same were urged.

— At the last meeting of the Saturday and Sunday Hospital Association it was reported that 293 churches

and synagogues had promised to make contributions this year. The reports from the various hospitals represented in the Association show that during the past three years \$201,651.44 has been expended on the enlargement of accommodations for patients; that there has been an increase in the income from invested funds of \$9780.12; that there has been an increase of income from paying patients aggregating \$43,036.72; that the increase of income from contributions toward current expenses other than derived from the Saturday and Sunday collection is \$22,774.84; that the total number of patients has increased from 8688 to 10,023, and that the total number of free patients has increased from 6698 to 7188. The statement is thus contradicted, which has been recently made in some quarters, and which is said to be based on London experiences, that the method of general collection fostered by this movement is inimical to the real interests of hospitals, in that it has a tendency to divert from them special gifts and bequests, because of the impression falsely conveyed that the one general collection is ample for the maintenance of all the hospitals benefited by it. The application of the New York Skin and Cancer Hospital for membership in the Association was formally acted upon.

— The twenty-ninth anniversary of the Woman's Hospital was celebrated at the wards of the institution on the 22d of November, when a bust of the late Dr. Marion Sims, by DuBois, of Paris, was presented by Mrs. Russell Sage, who said that it was almost thirty years since a memorable meeting was held in Stuyvesant Institute on Broadway, near Bond Street, and the outcome of that meeting was the Woman's Hospital, the first of its kind in the world. A physician, guided by the inspiration of the genius God had given him, had sought this city, bringing with him the results of faithful, conscientious toil which had achieved success in the cure of a pitiful and pitiless malady. It became their sacred duty to crown him Benefactor whom two continents had delighted to honor, and she hoped that the marble now presented would help to perpetuate in coming years the name of Dr. J. Marion Sims, the founder of the Woman's Hospital. After eulogistic remarks in regard to Dr. Sims by others, the report of the medical board was read, and showed that there had been 626 patients treated and 466 surgical operations performed in the hospital during the year ending October 1st; 4506 patients were treated in the out-door department.

— The fifteenth anniversary of the Presbyterian Hospital was held on the 18th. The principal address was delivered by the Rev. Dr. John Hall, who in the course of his remarks said that criticisms on the name of the institution as indicative of narrowness were disposed of by the annual report, which showed that of every hundred patients, fifty were Protestants of various other denominations, and the other fifty Roman Catholics.

— The twentieth annual meeting of the New York Society for the Relief of the Ruptured and Crippled was held at the hospital November 13th, when the medical report showed that during the year profes-

sional services were rendered 19,116 times to patients in the out-door department, and 126 visits made at the homes of those unable to attend at the hospital. The number of in-patients treated was 375.

— Dr. John C. Peters recently delivered a lecture on scarlet fever among horses at the Columbia Veterinary College, in which he made a more elaborate statement of his views than in his address at the annual meeting of the County Medical Society, his object being, as he remarked, to secure the coöperation of veterinary practitioners in investigating the subject, and its possible connection with the spread of the disease among human beings.

— The first case of small-pox in the city since last June was discovered by the sanitary authorities in a tenement house in West Fifty-ninth Street on the 16th of November. The patient had arrived from Ireland two weeks before.

— A public school situated in the Twenty-fourth Ward has been closed for a week by order of the president of the Board of Education in consequence of the death of the three children of the janitor of the building from diphtheria and the unusual prevalence of the disease in the neighborhood. All the children of the janitor were removed to another house as soon as the first case developed, but before the school is reopened the building is to be inspected, cleaned, and fumigated. The Health Board has not yet discovered that the Board of Education has adopted any radical measures in regard to seventy-five reports from sanitary inspectors setting forth that schools which had been inspected by them were unhealthy from defective ventilation, over-crowding, bad plumbing, and ill-constructed and ill-kept lavatories and closets.

— An outbreak of typhoid fever which is now in progress at Yonkers seems to be due to a great extent to contamination of drinking water, and the sanitary authorities have closed one public well into which there was found to be cess-pool drainage.

— Dr. D. A. Prohn has been fined \$100 for practicing medicine illegally. The diploma he presented was one of the fraudulent certificates issued by Paine's notorious "university" in Philadelphia some years ago.

MEDICO-LEGAL NOTES.

HYPERTROPHY OF THE PROSTATE FROM A FORENSIC POINT OF VIEW.

A QUESTION of some interest from a medico-legal point of view has recently been raised in connection with the criminal trial of a man, aged sixty-two, who was alleged to have banished his lawful wife, and filled her nuptial place by the substitution of his daughters, neither of whom was over twenty years of age. The specific charge of incest is not in point in the discussion, nor the claim of the girls that they yielded only to parental authority. The line of defense adopted for the accused was substantially that the sexual act could not have been performed because he was the subject of prostatic enlargement, which was in itself a bar to copulation inasmuch as it occa-

sions such pressure on the erectors penis as to draw the male organ downwards and render coitus impossible. The *Maryland Medical Journal*, November 17th, contains an article by Dr. Christopher Johnston in which this claim of the defense is discussed. Though the defense in this case was in many respects palpably lame, yet it suggests a point which in another case might have caused bewilderment of a jury. The death of the accused prevented the trial taking place, but an outline of the ground of defense had been made which the prosecution were prepared to meet.

In the first place it was denied that the defendant was the subject of prostatic enlargement, and an examination by experts was demanded, which the defense refused, claiming that such a condition was the regular thing in men of that age. On this point Dr. Johnston quotes many surgical authorities to the effect that prostatic hypertrophy is by no means the rule among old men, Sir Henry Thompson, for instance, declaring it to be present in only thirty-four per cent. of men over sixty. Moreover, the majority of writers, Astley Cooper being the principal exception, appear to believe this condition to be not so much the result of old age as of disease, and hence not to be presupposed by the mere fact of advanced years.

In the second place attention is called to the size attained by the organ in question, as also to the fact that whatever impediment is occasioned to the urinary flow none is alleged by any writers to exist to the generative act. In fact numerous authorities may be cited who speak of sexual excitability as a result of the enlargement of the prostate, and, conversely, one determining cause of the pathological condition in question is believed to be sexual excess. In fact, the concurrence of exalted sexual feeling with prostatic enlargement is much more frequent than any diminution of the former. Of course the advanced age at which prostatic hypertrophy is especially common is one when the sexual feeling naturally is to be expected to subside, and in certain cases the enlargement appearing at that time might suggest to the sufferer that it was the cause of his impotence. But evidence is wanting that the sexual function is any more impaired in old men with prostatic enlargement than in those of the same age who are free from it. The importance of the condition in question is held by all writers to lie chiefly in its effect on the urinary apparatus, and what sexual influence it does have is quite the reverse of what the defense in this case claimed.

Finally, as to the defense that the prostatic enlargement, by pressure on the ischio-cavernosi muscles, would draw the penis downward and render coitus impossible, it may be said that the function of these muscles is in dispute according to the different views of the method by which erection is normally effected. If one follows Quain's view of a passive congestion, due largely to compression of the base of the corpora cavernosa by these muscles, it is evident that a tension of the muscles such as the defense claimed would directly further erection. If, on the contrary, the process is considered more of an active congestion, due to dilatation of the sinuses through relaxation of

the trabecular muscular filaments, a tension of the ischio-cavernosus would conduce to erection according to Cruveilhier's view, for according to that author this muscle "acts solely upon the corpus cavernosum (of its side), drawing the root of the penis downward and backward; instead of compressing the root of the corpus cavernosum by the contraction of its fibres it tends, on the contrary, to dilate its cavity by separating the lower from its upper wall, and in this manner facilitates erection."

It would appear that the death of the accused was all that saved his counsel from disastrous failure in depending upon such a line of argument. Indeed, the suggestion occurs to one that a much more tenable defense in such a case, supposing prostatic hypertrophy to exist (which evidently would have to be established by examination, and could by no means be taken for granted from the age of the accused), would be that the disease of the prostate caused libidinous desires for which the accused was, therefore, not responsible. Erichsen says on this point:—

"The irritation of a congested and enlarged prostate will excite libidinous ideas in the aged, which may lead them to the perpetration of acts of indecency, such as exposure of the person, etc., or to a general impairment of the moral tone."

Correspondence.

PLAIN WORDS ABOUT THE MEDICAL REGISTER FOR NEW ENGLAND.

MR. EDITOR,—It may interest the readers of the *JOURNAL* to know that the *Medical Register*, which was started by me in 1873 as the *Medical Register* for Boston and vicinity, and has since expanded itself until it has become a professional handbook for regular medicine throughout New England, will be re-published within a few weeks, with appropriate additions, corrections, etc., to bring the book to date. The work is already under way, and reliable information and *subscriptions* will be called for at an early day. This work was undertaken and has been carried on by the author simply *for the good of the profession*. It offers no field for money making—*experto crede*—and all the author asks is that, in his next edition, he may be secured against making a loss. This can only be if the profession will come forward promptly, give him such information as is needed, and subscribe for, at the least, one copy apiece. The book will contain, in a small space, *a large amount* of information which every physician needs. It has been gathered with much labor, from sources inaccessible to the profession in general; and it will *pay* to own it.

The *Medical Register* will be issued at a rate lower than that of previous years, and will be offered by a well-known Boston house.

The announcement of a new edition is made at this time to correct the statements made by a person traveling in the interest of a New York firm for a *Medical Register* of Boston, who announces that the work, to which my name is attached, has ceased to exist.

FRANCIS H. BROWN, M. D.

Boston, November 30, 1883.

REPORTED MORTALITY FOR THE WEEK ENDING NOVEMBER 17, 1883.

Deaths reported 2343 (no reports from Cincinnati, District of Columbia, and Milwaukee): under five years of age, 774: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 427, consumption 337, lung diseases 276, diphtheria and croup 170, diarrhoeal diseases 74, typhoid fever 64, scarlet fever 41, malarial fevers 35, whooping-cough seven, erysipelas 10, measles nine, small-pox eight, puerperal fever seven, cerebro-spinal meningitis two. From *scarlet fever*, Philadelphia 17, Baltimore nine, New York six, Boston five, St. Louis four, Buffalo three, Chicago two, New Orleans, Pittsburg, Providence, New Haven, and Springfield one each. From *malarial fevers*, New Orleans 15, New York six, Brooklyn five, St. Louis four, Baltimore three, Philadelphia and Chicago one each. From *erysipelas*, Baltimore three, New York, Philadelphia, and Brooklyn two each, St. Louis one. From *measles*, New York four, Baltimore three, Brooklyn and Providence one each. From *small-pox*, New Orleans five, Nashville two, St. Louis one. From *whooping-cough*, Brooklyn three, New York and Philadelphia two each. From *puerperal fever*, Brooklyn, Chicago, Boston, St. Louis, Baltimore, and Worcester two each. From *cerebro-spinal meningitis*, Brooklyn and Providence one each.

Six cases of small-pox were reported in St. Louis; diphtheria 43, scarlet fever 43, typhoid fever 18, and measles seven in Boston.

In the 37 cities and towns of Massachusetts, with an estimated population of 1,420,336 (estimated population of the State 1,922,530), the total death-rate for the week was 12.81 against 17.50 and 19.08, for the previous two weeks.

In the 28 greater towns of England and Wales, with an esti-

mated population of 8,620,975, for the week ending November 3d, the death-rate was 20.1. Deaths reported 3328: acute diseases of the respiratory organs (London) 316, scarlet fever 139, diarrhoea 65, fever 72, measles 62, whooping-cough 44, diphtheria 21, small-pox (London and Birmingham three each, Wolverhampton and Liverpool one each, Sunderland four) 12. The death-rates ranged from 15 in Brighton to 30.2 in Preston; Birmingham 16.9; Bradford 17.1; Sheffield 18.7; London 19; Leicester 19.7; Nottingham 21.7; Liverpool 23; Leeds 24.3; Manchester 25.7; Newcastle-on-Tyne 26.2. In Edinburgh 19; Glasgow 25; Dublin 28.2.

For the week ending October 27th, in 170 German cities and towns, with an estimated population of 8,718,851, the death-rate was 22.3. Deaths reported 3732; under five years of age, 1736; consumption 488, lung diseases 344, diphtheria and croup 307, diarrhoeal diseases 163, scarlet fever 87, whooping-cough 68, typhoid fever 61, measles and *rötheln* 47, puerperal fever 23. The death-rates ranged from 7 in Karlsruhe to 42.1 in Duisburg; Königsberg 34.6; Breslau 23.8; Munich 27.3; Dresden 23.6; Berlin 23.4; Leipzig 25.3; Hamburg 21; Cologne 20.6; Frankfurt a. M. 13.4; Strasburg 21.

For the week ending November 3d, in the Swiss towns, there were 26 deaths from consumption, lung diseases 16, diarrhoeal diseases 14, typhoid fever five, whooping-cough two, diphtheria and croup two, measles one. The death-rates were, at Geneva 17.4; Zurich 14; Basle 15.9; Berne 23.7.

The meteorological record for the week ending November 17th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps:—

Deaths reported 2696 (no report from New Haven): under five years of age, 898: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 522, consumption 418, lung diseases 297, diphtheria and croup 213, diarrhoeal diseases 69, typhoid fever 65, scarlet fever 65, malarial fevers 42, whooping-

cough 20, measles 18, small-pox 11, cerebro-spinal meningitis eight, erysipelas seven, puerperal fever three, typhus fever one. From scarlet fever, Philadelphia 14, New York and Buffalo nine each, Boston eight, Baltimore six, Brooklyn and Chicago five each, St. Louis two, Cincinnati, District of Columbia, Milwaukee, Providence, Lowell, Worcester, and Cambridge one each.

From *malarial fevers*, New York 14, New Orleans nine, Brooklyn and St. Louis six each, Baltimore three, Charleston two, Philadelphia and Chicago one each. From *whooping-cough*, New York eight, Brooklyn three, Boston, Baltimore, and New Orleans two each, Philadelphia, District of Columbia, and Milwaukee one each. From *measles*, New York seven, District of Columbia six, Chicago and Baltimore two each, Pittsburg one. From *small-pox*, New Orleans 10, Philadelphia one. From *cerebro-spinal meningitis*, New York and Chicago, three each, Worcester and Fall River one each. From *erysipelas*, Baltimore five, Boston two. From *puerperal fever*, Chicago, Boston, and St. Louis one each. From *typhus fever*, Milwaukee one.

Nine cases of small-pox were reported in St. Louis; Boston one; scarlet fever 44, diphtheria 28, typhoid fever 23, measles two in Boston; diphtheria 25, and scarlet fever 19 in Milwaukee.

In the 45 cities and towns of Massachusetts, with an estimated population of 1,208,250 (estimated population of the State 1,922,530), the total death-rate for the week was 18.59 against 12.81 and 17.52 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending November 10th, the death-rate was 21.5. Deaths reported 3547: acute diseases of the respiratory organs (London) 365, scarlet fever 160, fever 76, measles 70, diarrhoea 65, whooping-cough 49, diphtheria 34, small-pox (London two, Birmingham and Sun-

derland one each) four. The death-rates ranged from 13.4 in Derby to 31.4 in Newcastle-on-Tyne; Leicester 18.1; Birkenhead 18.8; Nottingham 19.1; Bradford 19.4; Birmingham 19.9; Sheffield 20.1; London 20.5; Liverpool 24.7; Manchester 27.8; Leeds 28.1. In Edinburgh 22.1; Glasgow 23.3; Dublin 25.8.

For the week ending November 3d, in 166 German cities and towns, with an estimated population of 8,702,430, the death-rate was 22.6. Deaths reported 3780; under five years of age, 1170; consumption 444, lung diseases 303, diphtheria and croup 269, diarrhoeal diseases 162, scarlet fever 118, typhoid fever 82, whooping-cough 64, measles and röteln 55. The death-rates ranged from 12.1 in Darmstadt to 34.3 in Posen; Königsberg 35.5; Breslau 29.1; Munich 23.8; Dresden 25.4; Berlin 25.3; Leipzig 24.7; Hamburg 18.2; Cologne 21.3; Frankfurt 17.1; Strasburg 19.1.

For the week ending November 10th, in the Swiss towns, there were 22 deaths from consumption, lung diseases 20, diarrhoeal diseases nine, diphtheria and croup four, whooping-cough two, erysipelas two, typhoid fever one, scarlet fever one. The death-rates were, at Geneva 9.2; Zurich 8; Basle 15.1; Berne 21.5.

The meteorological record for the week ending November 24th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps:—

Date.		Barometer.	Thermometer.			Relative Humidity.			Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.		
		Daily Mean.	Daily Mean.	Maximum.	Minimum.	7.23 A. M.	3.23 P. M.	11.23 P. M.	Daily Mean.	7.23 A. M.	3.23 P. M.	11.23 P. M.	7.23 A. M.	3.23 P. M.	11.23 P. M.	7.23 A. M.	3.23 P. M.	11.23 P. M.	Duration. Hrs. & Min.	Amount in inches.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING DECEMBER 1, 1883.

KINDLEBERGER, D., medical inspector, to be relieved from duty on the Retiring Board on December 9th.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM NOVEMBER 23, 1883, TO NOVEMBER 30, 1883.

WOLVERTON, WILLIAM D., major and surgeon. Assigned to duty as post surgeon at Washington Barracks, D. C. Paragraph 7, S. O. 222. Department of the East, November 27, 1883.

BROWN, PAUL R., captain and assistant surgeon. Assigned to duty in the Department of Arizona. Paragraph 4, S. O. 273. A. G. O., November 28, 1883.

MERRILL, JAMES C., captain and assistant surgeon. Relieved from duty in the Department of the East, and assigned to duty at Columbus Barracks, Ohio. Paragraph 4, S. O., 270. A. G. O., November 24, 1883.

APPEL, A. H., first lieutenant and assistant surgeon. Relieved from duty at Fort Warren, Massachusetts, and assigned to duty at Madison Barracks, N. Y. Paragraph 4, S. O. 217. Department of the East, November 21, 1883.

BREWSTER, WILLIAM B., first lieutenant and assistant surgeon. Extension of leave of absence granted September 15, 1883, further extended two months. Paragraph 4, S. O. 271. A. G. O. November 26, 1883.

MADDOX, THOMAS J. C., first lieutenant and assistant sur-

geon. Granted leave of absence for two months. S. O. 136. Department of the Missouri, November 24, 1883.

SUFFOLK DISTRICT MEDICAL SOCIETY.—The Section for *Clinical Medicine, Pathology, and Hygiene* will meet at 19 Boylston Place, on Wednesday, December 12th, at 7.45 o'clock. The following papers will be presented: Dr. G. M. Garland, The Treatment of Follicular Tonsillitis. Drs. F. I. Knight, S. W. Langmaid, and J. P. Oliver will open the discussion. Dr. E. O. Otis, The Use of Tobacco Among Boys. Dr. H. I. Bowditch and Dr. A. C. Gorgas (Medical Inspector, U. S. N.) will open the discussion. H. A. Baker, D. D. S., will exhibit an improved appliance in the physiological treatment of Cleft Palate, illustrated upon a patient. ALBERT N. BLODGETT, Secretary.

BOOKS AND PAMPHLETS RECEIVED.—The Oyster Epicure. A Collation of Authorities on the Gastronomy and Dietetics of the Oyster. New York: White, Stokes & Alden. 1883. Sepulture: its History, Methods, and Sanitary Requisites. By Stephen Wickes, A. M., M. D. Philadelphia: P. Blakiston, Son & Co.

Manual of General Medicinal Technology, including Prescription-writing. By Edward Curtis, A. M., M. D. New York: Wm. Wood & Co. 1883.

A Handbook of Therapeutics. By Sydney Ringer, M. D. Tenth Edition. New York: Wm. Wood & Co. 1883.

A Case of Severe Purulent Inflammation of the Middle Ear, with Restoration of the Drum-head. By Edward S. Peck, M. A., M. D. Reprint. New York.

TINNITUS AURIUM AND VERTIGO AS PROMINENT SYMPTOMS OF LITHÆMIA.

BY GEORGE H. LYMAN, M. D.,
Physician to Boston City Hospital.

THERE is perhaps no class of patients coming under a physician's observation which are more troublesome than those cases of gastric and hepatic derangement due to the lithic acid diathesis so-called. The functional disturbances are so associated with nervous phenomena as to render the sufferer impatient and intractable, skeptical of your assertion that he has no serious organic disease, and ready to try every nostrum and accept every diagnosis but the true one from the numerous professional and lay friends whose sympathy he seeks.

Although lithæmia, lithuria, lithiasis, etc., have now become tolerably familiar terms to the profession, the whole subject still remains more or less obscure; especially the subjective semiology and the relative importance of the renal and hepatic pathology. The true nature of the affection often escapes recognition by the medical adviser until some case presents itself which cannot be ignored, when he is forced to closer inquiry into the antecedents and a more rigid analysis of the symptoms. He then discovers that he has to deal with something more than a mere gastric derangement, indigestion, dyspepsia, or what not, vague terms with which he has temporarily satisfied his own conscience and his patient's importunities; his blue pill and pepsin, his alkalies and sedatives, either separately or in some incongruous combination, have generally been a lamentable failure. In mild cases, to be sure, the mark is occasionally hit by some snap shot, but when the patient, superadded to his other grievances, has an incessant tinnitus, he loses faith in the stomach doctrine, or if his memory begins to suffer, or he has occasional attacks of vertigo, so sudden and severe as to make him unwilling to trust himself alone in the street, what wonder that he should seek other and special skill in brain, heart, eye, or ear, to the great discredit of the general practitioner; for though he may get no more relief by the change, his subjective symptoms get more direct attention and he, at any rate, is for the time being satisfied that merely local treatment is exactly what he needs.

While the first of the following cases was under observation the admirable article of Dr. DaCosta appeared in the October number of the *American Journal of Medical Sciences* for 1881, in which these nervous phenomena especially are brought more prominently forward than in the famous Croonian Lectures of Dr. Murchison, which have done so much by stimulating inquiry to develop our knowledge of these lithæmic conditions. Although I cannot hope to add anything to the value of Dr. DaCosta's paper, possibly some allusion to a series of my own cases may be of interest to others.

The disorder in question has no fixed set of symptoms. The subjective expression of the pathological condition may manifest itself in protean forms. Either the gastric, rheumatic, renal, hepatic, cerebral, or cardiac, or several of them combined, may seem to predominate in any particular case, yet each is dependent

in great measure upon certain lithuric conditions, which, being neglected, render any treatment unsatisfactory if not wholly useless. It is not necessary that nausea, constipation, or diarrhoea, headache, insomnia, or palpitations, myalgic pains, or urinary deposits, should all be present in any given case; the subject of it indeed is quite likely to express himself as being otherwise in good health and strength, vigorous in mind and body, and yet so tormented at times, and apparently without cause, with one or more of the functional nervous phenomena described, as to induce in him the fear of some fatal organic defect of heart or brain.

Of the varied symptoms none are more distressing than the two which are the more immediate subject of this paper: a constant tinnitus aurium from which there is no escape during the waking hours, and which indeed often interferes with the sleep, — buzzing, ringing, clicking, or constant pulsation, for which no visible nor tangible cause can be discovered either in gastric disorder or the external and internal auditory apparatus, — is not only a constant source of annoyance but of serious apprehension to its unfortunate possessor; or still more if either with or without this tinnitus the victim finds himself the subject of sudden attacks of vertigo, so severe and decided as to cause a staggering gait, possibly complete prostration, as an attack of epilepsy, the case assumes a gravity which startles and terrifies its subject into fear of impending death.

In one case a young, active, business man, apparently in vigorous health, in addition to some of these symptoms finds his memory failing to such a degree as to impair business efficiency; he cannot recall the prices of his goods, the daily changes in stocks, etc., and fancies that he is threatened with paralysis, brain softening, or some dire evil which is to bring ruin upon him.

Another will have renal complications dependent wholly upon some hepatic derangement of function which sends him from one physician to another in the hope of relief to his fear of Bright's disease, diabetes, or cystic calculus, while still another may be complicated solely with tormenting muscular or arthritic pains. And so on one might recall instances of one or more of these with the addition of purely nervous complications, simulating to the fears of the patient almost every conceivable organic disease.

The first of the ensuing cases only is given in some detail, it being a striking instance of the disorder, and one which with its coincident organic cardiac complication might well have caused much concern to both physician and patient, but which, when its true nature was appreciated, proved to be susceptible of prompt and effectual relief.

Dr. —, who had been in active practice for twenty-five years, about 1871 was attacked suddenly, after a moderate lunch, with vertigo so decided as to necessitate the recumbent posture, and cause great alarm to his family. There was no actual syncope, but a distressing sense of faintness, from which, however, he recovered in a few minutes; there was neither nausea, palpitation, nor headache. The attack was at the time attributed to lager beer, not very fresh, taken with the lunch. In early life, while a medical student, he had suffered from a bad attack of endocarditis entailing mitral disease during the course of a severe rheumatic fever. Three or four years later he had a second rheumatic seizure, very severe, and lasting, with little intermission, for six weeks, but without any addi-

¹ Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Suffolk District Medical Society, November 14, 1883.

tional cardiac complication. Since these attacks any unusual exertion has inevitably induced palpitations and dyspnoea, but with the precautions which his professional knowledge indicated these attacks were infrequent, giving but little trouble and no apprehension. At about the period of the first vertiginous seizure he began to be troubled with tinnitus, but at rare intervals, and coincident with catarrhal attacks, nasal and faucial. For a time this attracted little attention, but subsequently became more frequent and annoying until, at the end of some years, the tinnitus became almost constant through the day, and at night was frequently so annoying as seriously to interfere with sleep. Consulting his friends specially skilled in aural affections, it was by all agreed that the cause must be attributed to an extension of the catarrhal congestion to the middle ear, with fibroid thickening of the canal, and that in view of its long duration little encouragement could be given for its permanent relief. The verdict was, perforce, accepted, and for years the continued singing was endured with such philosophy as could be mustered, though occasionally the pulsations would become so aggravated as to be almost unendurable. From 1871 to 1879 occasional attacks of vertigo occurred, but generally late in the evening, and after days of unusual fatigue. These were always temporarily relieved by a drachm or two of any mild stimulant. The attacks were at one time thought to be possibly due to his habit of smoking, but no direct relation could ever be traced. In 1879, when leaving the water-closet one morning, a sudden and severe attack occurred with distressing faintness and prostration, though the pulse was of good strength, and there was no palpitation. Some time elapsed before he was able to leave the floor for a couch, and subsequently to resume his daily work, in the pursuit of which he now, for the first time, noticed that his gait was uncertain. For the ensuing two years there were no more or only very slight attacks of vertigo, but the sense of inability to walk straight was more or less manifest, and at times to so great a degree as to make him fear the charge of intoxication. The staggering could only be overcome by stopping, sitting down, or grasping the first tree or fence for a few minutes.

Finally, in October, 1881, when apparently perfectly well, there being neither gastric nor cardiac symptoms, a very sudden and severe attack of vertigo occurred while walking through a hospital ward, and a chair at hand alone prevented his falling. The faintness was relieved by a swallow of brandy, and the visit finished without difficulty.

Matters had now assumed so grave an aspect that he began seriously to study his own case, as he would have been compelled to do in the case of any other patient. First the condition of the heart was investigated as a possible cause, but competent examination revealed no increase of the old mitral disease, no evidence of fatty degeneration, the pulse in fullness, frequency, and rhythm normal, neither palpitations nor dyspnoea. No evidence whatever of any organic cerebral disorder. The renal function was apparently perfect; the urine of proper specific gravity, and normal in quantity, although there was a tendency to abnormal acidity. In the absence of any deposit or other symptoms the urine was only roughly tested at any time; unfortunately no accurate analysis was ever made. The digestion was vigorous; the bowels, as always during life, regular with exceptions noted hereafter. I should

now state that since the two rheumatic seizures in early life, above mentioned, he has been subject to frequent attacks of pain and swelling in the small joints of hands and toes, more especially the former, and also to myalgia in shoulders, loins, and hips. These have never been accompanied by fever nor by any severe disturbance of the general health, but always by extreme irritability, nervousness, and impatience, with more or less torpor of the bowels. The appetite, even in the worst of these, was always good enough, if not too good. These attacks were usually directly traceable to indulgence in certain articles of food or drink, and never found susceptible of mitigation by drugs of any kind until these special things were omitted for a time. Half a bottle of claret or burgundy, for instance, would almost certainly induce redness, swelling, and pain in the knuckles, sometimes on a single trial, more often at the end of a few days; strawberries always, and most other fruits if eaten after meridian; malt liquors of any kind if used continuously; while, on the other hand, the moderate long-continued use of brandy, whiskey, thin, dry sherry, or dry champagne agreed perfectly if taken in moderation with dinner.

The sharp gouty pains and enlargement and redness of the smaller joints in connection with the nervous irritability suggested, of course, the lithic acid diathesis, and careful continued observation proved a direct connection between the exacerbations and increased tinnitus and vertigo.

A more careful course of diet was at once instituted. The amount of nitrogenous and carbonaceous food was greatly reduced, and all stimulants and malt liquors, always in daily, but never in excessive, use, were discarded entirely. As medicines a full dose of citrate of lithia was given before each meal, and an active dose of bitter water on rising each morning, the latter producing one full liquid evacuation daily. The effect of this course was very decided. It was continued with hardly an intermission for four months, though on several occasions, when too much animal food or a glass or two of claret, sherry, or madeira were indulged in, the warnings were unmistakable. At the end of this period the tinnitus was hardly noticeable, the vertigo entirely gone, and the gouty pains a thing of the past. For the past year his health has been more vigorous than ever, but only at the price of constant watchfulness, for any attempt at the indulgences of the table, either at once or with the lapse of two or three days, brings its penalty in arthritic pain, tinnitus, or vertigo, one or all.

The only wines that seem to cause no trouble are a thin table sherry and dry champagne. Better than either is a tablespoonful of brandy with dinner, which seems to be not only harmless but a positive benefit.

I make no apology for giving this case at some length, as I consider it to be a good illustration of a certain class of lithæmic cases, and typical of the nervous and gouty complications while remarkably free from those renal and gastric symptoms which more generally accompany and obscure the diagnosis; for, as will be noticed, there were none of the ordinary symptoms to call attention to what was undoubtedly the true source of the difficulty, the imperfect assimilation of the ingesta. That vertigo and tinnitus as well as other obscure and intractable complaints, especially those of the skin and mucous membranes, may often be traced to this so-called lithuric condition, whether it be designated as lithæmia or suppressed gout, there can be

no doubt. I could give from my notes many other cases in which the relief from distressing symptoms of long duration, and where the sufferers had become almost hopeless of relief, would be shown, but the narration would serve no other purpose than to lengthen this already tedious paper, if given in detail. I will merely allude to a few of them, as showing some of the common differences in type:—

I. The son of a physician, married, aged forty-six, a high liver, had for three years been subject to these nervous symptoms. In this case renal congestion was so marked a feature as to cause apprehension of some organic disease of the kidneys. Under proper treatment the functions of the liver were restored, the nervous and renal symptoms disappeared, and he regained, and so far as I know is still in, comparatively vigorous health.

II. A perfectly temperate man aged fifty-six, was for two years subject to vertigo. He had also muscular debility, nausea, and some anasarca. Under careful regulation of the diet, free action of the bowels, nitromuriatic acid, etc., the vertigo and muscular weakness disappeared and his apprehensions with them.

III. A lady of middle age, with some suspicious renal symptoms, headache, nausea, cedema, etc., was under my care at intervals for two years. Early in 1882, though much improved in many respects, the nausea especially having nearly disappeared, she consulted me again for frequent and painful micturition and incessant tinnitus aurium. By the use of lithates with whiskey and cream and a restricted diet, iron and aloes, and bitter water, she obtained relief from all the nervous complications.

IV. A well-nourished and apparently vigorous man of thirty-two, in active mercantile life, complained bitterly of seminal emissions and loss of venereal appetite but chiefly of a constant sense of cerebral confusion, with loss of memory, at times so absolute that he could not remember the prices of his merchandise or make simple arithmetical calculations. He was married, and of steady habits, excepting that his meals were irregular and hastily eaten. He suffered to a slight degree from hæmorrhoids and headache. The emissions proved to be trifling and distinctly prostatic, not seminal. As he was an excessive smoker, tobacco was forbidden, and with proper regulation of the quantity and quality of his diet and the use of saline laxatives and mineral tonics, the unpleasant cerebral phenomena were relieved entirely and permanently, a year having now elapsed without any recurrence.

V. While writing this paper a somewhat similar case occurs to me, not of vertigo but of most unpleasant cerebral confusion, occasional attacks of distressing tinnitus, with muscular pains, tenderness and swelling of the small joints, and an increased renal secretion, with painful micturition. There has also been on several occasions a decided loss of power in the extensors of the fore-arm. The patient has been under my charge at intervals for ten years, and has had repeated recoveries from and recurrences of these symptoms, and will probably continue to have them to the end, for being of ample means and extremely indolent habits the requisite perseverance in treatment is not attainable. It is sufficient to say that the tinnitus and other symptoms in her case always and readily yield to the treatment indicated so long as it is persevered in.

VI. I will allude to but one more. An old gentleman past seventy has been for many years a notable

specimen of the hypochondriac. He has, however, certain difficulties that are not imaginary, especially prostatic enlargement in an aggravated degree. He has for years suffered from tinnitus, slight vertigo, palpitations, and an aggravated catarrh of all the mucous membranes from the *alæ nasi* to the pylorus. He was under my care for a year or two before I could get him under decent control. He was depressed, skeptical, sure that he was to lose his mind or die suddenly of apoplexy or heart disease, would follow a prescription for a day and then seek another; buy every quack medicine that was recommended (and serve it, fortunately, in the same way), until finally, under the threat that I could or would do no more, a promise of obedience was exacted and tolerably kept until now, under comparatively simple treatment, life is no longer a burden to him or his friends, the tinnitus and vertigo, the catarrhal troubles and cardiac irregularities, being immensely relieved.

The object of this paper is to call attention to those lithæmic cases in which tinnitus and vertigo are prominent symptoms, they being the most alarming and distressing to the patient of the nervous phenomena induced by an excess of lithic acid in the blood.

Many cases of tinnitus, no doubt, are temporary, such, for instance, as are caused by slight gastric derangement, an excess of ceruminous deposit, local congestions, etc., while other and incurable cases are due to actual organic changes in the auditory apparatus, and the same remark will apply to many cases of vertigo, whether from an acid stomach or actual fatty degeneration of the circulatory apparatus; but other than these, I can recall many instances occurring in former years, where, not suspecting what I now believe to have been the true cause, I was unable to afford that relief which I am confident would have followed a more accurate diagnosis.

How in deranged function of the liver imperfect disintegration and oxidation of the albuminoids results in the excess of lithic acid in the blood is a physiological problem, for the discussion of which I must refer to Flint, Draper, Bence Jones, Fothergill, Charcot, Murchison, and many others. The opinions of writers and experimenters are as yet quite at variance upon many points. A few remarks only are needed in this connection for the purposes of this paper.

And first, it is not sufficient to say that tinnitus is due to deranged circulation or irregular muscular action, for though both are probably true, what is the cause of those derangements; and so of vertigo? We must go farther back and find what causes are at work in the blood to influence the vaso-motor and trophic processes. An embolus in the middle cerebral we say results in aphasia, but we mean that aphasia is due to deficient nutrition in the brain cells.

That an excess of nitrogenous and carbonaceous foods, or, there being no excess, a relative deficiency of oxygen, results in imperfect oxidation seems probable. Were the oxidation complete, instead of insoluble lithic acid we should get soluble urea for normal elimination by the kidneys.

On the other hand, we have the opposite view¹ that an undue prominence has been given to uric acid in these gouty or lithæmic cases; that the difficulty rests rather with its insolubility than in its excessive production; that it is a consequence rather than a cause; and that the saccharine rather than the nitrog-

¹ See Ralfe on Morbid Urine, pages 65-98.

enous elements of the food are the most mischievous. However this may be, the kidneys seem to play an eliminatory rôle chiefly, although it must be remembered that the necessary excess in activity may lead eventually to chronic congestion and secondary organic changes of structure.

The vaso-motor and trophic influences, the mode of distribution, as well as the nutritive quality of the blood, become also important factors in the production of the cerebral symptoms under discussion. If the blood of the living body should be always alkaline it is not difficult to see that an abnormal excess of lithic acid would create these vaso-motor or trophic disturbances, one or both, in the circulation and nutrition of the brain and cord, a diminished alkalinity, whether relative or absolute, diminishing the contractility of the heart.

As to treatment, it is already sufficiently indicated, if we accept the theory of the lithæmic origin of the trouble. That the liver may rest from its overcharged labor, saccharine, nitrogenous, and alcoholic ingesta must be diminished, both sedentary habits on the one hand and excessive fatigue on the other, and over cerebral exhaustion from study or worry avoided, they all tending to weaken the circulation, and so favor acid accumulation.

With regard to the use of tonics, mineral or vegetable, they are often worse than useless, especially in the early stage of average cases, in which, with a careful diet, mild saline laxatives perseveringly used are the best tonics. In anæmic or broken-down cases their use may be, of course, a necessity.

In most cases alkaline salts are indispensable, and of these I have found citrate of lithia as useful as any, and perhaps the most agreeable to the stomach, although occasionally it overstimulates the kidney and must be suspended for a time, or replaced by soda or potash, taken an hour after meals, these being in all cases preferable when much flatulence is complained of. Salicylate of lithia I have not yet tried.

Where the pain is myalgic, muriate of ammonia in full doses will often give prompt relief, though if this result does not follow within a day or two, its continuance is useless. I have found no benefit from it in arthritic pain, or tenderness. Mercurials, podophyllin, colchicum, etc., must, I think, be rarely needed, and are objectionable from their depressing effect. Their influence upon the biliary secretion is at least questionable, and if the small intestines are kept free from biliary accumulation by saline or other laxatives, such as ipecac, rhubarb, and soda, they are not required. If there be any one thing which I should lay the most stress upon throughout the treatment, it would be the use of aperient bitter waters. Nothing proves so promptly effectual in removing those exacerbations of arthritic tenderness, vertigo, and tinnitus, which the most tractable patient will occasionally bring upon himself by some indiscretion, as an extra dose of Hunyadi or Pullna water taken for a day or two in the morning fasting. By an extra dose I mean a larger and more active one, for I would have a smaller dose of the same used almost continuously and for months after the cessation of the urgent symptoms. These waters keep the small intestines free, and the sulphates of soda and magnesia with which they are highly charged have a cholagogue influence which goes for something. Their influence as combined in these waters is decidedly more

satisfactory than when taken alone. The Carlsbad or Sprudel salts may also be mentioned in this connection, especially as they have been recently discovered to contain lithia, which the others do not.

The aggravated catarrhal complications may now and then require especial treatment, but in a large proportion of cases the troublesome nasal and faucial congestion will be found to yield with the lithæmia on which it depends.

As to the use of stimulants most patients are probably better for entire abstinence, but in a certain class such abstinence can with difficulty be enforced. I know of no rule by which one can be guided but the experience of the patient himself. As a rule, of the light wines the driest are the best. One will drink claret with impunity, while to others it is an undoubted poison, and the same may be said of champagne, burgundy, hock, etc. Climate and especially hygrometric conditions become here, I believe, an important factor. It is now a well-known fact that a patient will indulge with impunity in England or on the Continent in beverages both in quantity and in quality which in our drier climate cannot be assimilated. The first case reported was a striking instance of this, as was proved by his experience in repeated visits abroad.

In certain cases stimulants with iron or bark and acids may, as I have said, become a necessity, especially if the alkaline treatment induces any marked impoverishment of the blood, for in all cases a lowering treatment is to be avoided. It must not be forgotten that one's living may be generous without being excessive in either food or drinks.

The patient should always be made to understand that the relief which he may receive is to be permanent only so long as the conditions of the cure are complied with, and that any indulgence or excess will almost inevitably be followed by its penalty, and moreover, remembering that too frequent recurrences of merely functional disorder are likely to result eventually in actual organic changes no longer amenable to curative treatment.

In conclusion I may be permitted to say that while the pathology of these affections remains as at present an open question with different observers, the successful treatment of a series of cases may help materially in its solution. Where medical science is defective medical art may assist in placing it upon a right foundation.

RECENT VIEWS RESPECTING THE DIAGNOSIS AND TREATMENT OF LITHÆMIA.¹

BY JAMES J. PUTNAM, M. D.

It is well known that a tendency has been manifest of late among medical men in this country, as for a long time past in England, to diagnosticate as suppressed gout, or lithæmia, cases presenting a great variety of nervous symptoms, often anomalous and distressing in character, generally occurring in patients of gouty, but sometimes even in those of non-gouty, descent.

This tendency has been met in many quarters with incredulity, and some men of conservative temperament would be well content to let the matter slip by with a verdict of non-proven. Where no overt gout exists it is gratuitous to assume suppressed gout, they

¹ Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Suffolk District Medical Society, November 14, 1883.

say, and the argument seems especially applicable to this country and generation, in which overt gout is so rare. Such an attitude seems to me to involve the disregard of clinical facts of manifest importance, yet I admit that even this is better than to abandon one's adherence to the laws of evidence for the sake of a plausible hypothesis. It is evident that there is a middle ground to be discovered, and it is important, in the interests of practice as well as theory, that its limits should be defined as accurately as possible.

Two questions naturally suggest themselves for solution in this connection; first, what are the ascertained facts in the matter; second, what are the inferences which involve the least infraction of sound reasoning.

The conclusions which seem to me the best established are:—

(1.) That various nervous symptoms, and symptom-groups (as well as certain affections of the skin and mucous membranes) may be due to disorders of nutrition of the body at large, and are best treated from that stand-point.

(2.) That, however, it has not been shown, nor rendered especially probable, that these symptoms are apt to be due to an excess of uric acid in the blood, except in so far as they occur in true gout.

(3.) That the effects of treatment in cases of so-called lithæmia are not such as to lend much support to the belief that it is a specific disease.

(4.) That there is abundant justification by analogy for the view that the impaired health found in the families of gouty persons need not itself be of a gouty nature.

(5.) That most, if not all, of the so-called lithæmic symptoms may and often do originate in a primary disorder of the nervous system (including true neurasthenia).

It will be worth while, to begin with, to glance briefly at the few advances which have been made in the pathology of true gout during the past few years.

It is well known that the one discovery bearing on this subject which has been able to maintain itself, almost unassailed, is that announced by Garrod in 1848, that the blood of gouty patients contains uric acid.

The explanations by which he proposed to account for the outbreaks of the disease, namely, that diminished excretory power of the kidneys caused a further accumulation of the uric acid in the blood, and that diminished alkalinity of the blood caused the precipitation of urate of soda in the tissues, have not fully stood the test of criticism. They remain as unproved, indeed as improbable, though noteworthy speculations.

It is, however, worth bearing in mind that diminished alkalinity of the blood such as is supposed to arise from dyspepsia with constant formation of acid products in the intestinal tracts, though it may not cause gout or lithæmia, has been regarded as accounting for a variety of nervous symptoms such as are usually attributed to suppressed gout. This is a view taken, for example, by Dr. Ralfe in his interesting little book on Morbid Urine.

Garrod's original researches left the origin of the uric acid unknown, though he believed that the kidneys themselves should be exonerated.

In 1874 Murchison delivered his able and suggestive Croonian Lectures on Functional Diseases of the Liver, and then first proposed, I believe, the term *lithæmia*. Murchison's aim was to show that, among its other important functions, the liver was the great laboratory for the conversion of nitrogenous compounds

into urea, and inasmuch as uric acid resembles urea except in containing less oxygen, and may even be converted into urea, it was maintained that uric acid was one of the suboxidation products of albumen-metabolism, and that the liver might be considered responsible for all the range of diseases, from chronic bronchitis and dyspepsia to gout and chronic Bright's disease, which could be laid to the door of the baneful uric acid and its congeners in the blood.

The liver is still admitted to be the seat of much chemical change, and the efforts of Murchison no doubt did much to clear its somewhat rusty clinical reputation, and to call general attention to its important functions and diseases. Yet, in spite of the guarded support of Charcot a few years later, Murchison's theory of hepatic lithæmia has not taken the place in pathology which its author claimed for it. The suboxidation part of it, which is for us the important portion, deserves especial consideration, since it concerns the doctrines of the treatment of gout as well as of its pathology.

It is now almost universally regarded as probable that in health uric acid and urea are parallel and normal products of albuminous disintegration, and not simply representatives of different states in one process.¹ Increasing the oxygen supply makes no difference in the oxidation of uric acid. The amount of oxygen in the blood does not in fact determine the amount of chemical change in the body, but is determined by it, the oxygen being called in only to repair the waste already caused.² The oxidation of nitrogenous compounds is a function of the tissues, and its activity is measured by the number and efficiency of the cells of which the tissues are composed. The oxygen by which this is accomplished is stored up in the tissues. The oxygen in the blood serves to feed this reservoir, but to this end there is always enough unless the blood is actually starved, as in asphyxia.³ Similarly, the reason why carbonaceous food is not good for gouty persons (when such is the case) is not because it attracts the oxygen which would have gone to complete the oxidation of the albumen, but for more complex reasons.⁴

Setting aside, however, the special question of the relation of uric acid to urea, it is quite true that the general doctrine that disease of various kinds (renal, among the rest) may arise from the presence in the circulating fluids of the results of imperfect metamorphosis of food, still holds a respected place among pathologists, as an important, although as yet unproved, hypothesis. As a practical matter, it is certainly very proper that in any doubtful case we should make every effort to improve the efficiency of the tissues to convert and assimilate food, both directly, by acting on the tissues and the circulation, and indirectly, by modifying the quality and quantity of the food, and there are good clinical reasons for thinking that in this way we shall often succeed in removing obscure nervous symptoms, but this admission is by no means equivalent to the adoption of the prevailing theory of lithæmia.

Within the past year our knowledge of the gouty processes has been enriched by two important investigations, carried on respectively by Garrod,⁵ and by Ebstein,⁶ Professor of Clinical Medicine in Gottingen.

Garrod's investigations were mainly directed to the question of the relation of the excretion of uric acid to the formation of calculi, but in the course of them he makes some interesting statements about the amount of uric acid excreted by birds, which seem to prove that in them this substance must be formed in the kidney itself; and if in them, he thinks, then in all probability in man also, contrary to his former view. The quantity of this excretion in certain birds is indeed enormous, the daily amount being sometimes more than the whole weight of the kidneys. Knowing the average amount which the blood contains, and calculating the number of times that the kidneys refill themselves with blood in the course of the day, Garrod confidently affirms that they could not in that way obtain a sixth part of the uric acid which they excrete. He claims also to have found that the reason that the urine of herbivorous animals contains no uric acid is because they form hippuric acid from their food, and affirms that the uric acid excreted by man is greatly diminished, or made to disappear, if benzoic acid, a congener of hippuric acid, is taken by the stomach, a suggestion important for the treatment both of calculus and gravel, and of true lithæmia. The more recent experiments of E. Alleyne Cook¹ indicate that benzoic acid does not really destroy uric acid, but only prevents its precipitation by acidulation.

The able investigations by Ebstein are largely experimental in character. He fully indorses the uric acid theory of Garrod, and makes it probable that the uric acid salts, even while still in solution, impair the nutrition of the tissues through which they pass, and if in concentrated solution, impair them (as proved to be possible by actual experiment) to such an extent that the life of the tissues is destroyed, and in dying develop an acid reaction which causes the precipitation in them of the urate of soda. To this irritating action of these salts in solution in the blood he thinks the various symptoms referable to affections of the mucous membranes, the nervous system, the walls of the blood-vessels, etc., are due, and in fact he fully gives in his adherence to the doctrine of lithæmia *in the gouty*. The uric acid he believes to be formed not in one alone but in many organs, among which are to be reckoned (in gout, though not under normal circumstances) the marrow of the bones, and the muscles. Ebstein regards gout, therefore, as a disorder of nutrition in consequence of which uric acid is formed abnormally in the bones and muscles. He considers it analogous to cystinuria, or to diabetes, but does not recognize the agency of any underlying neurosis which various writers, and especially Dr. Duckworth,² have assumed. He extends widely the rôle played by uric acid, about as widely, in fact, as any of the English writers, but would say that without uric acid no gout. At the same time he thinks that this excessive production of uric acid may remain through life without causing symptoms of any kind, if no exciting cause comes in to provoke them.

The arguments by which Dr. Duckworth,² who is able to array a number of the highest authorities on his side, endeavors to prove gout to be at bottom a *tropho-neurosis*, either primary and inherited or secondary and induced by blood-poisoning, are ingenious and forcible, but of such a nature that it would be impossible to reproduce them here at length. He

thinks that without invoking the periodic action of the nervous system it is impossible to explain the outbreaks of the attack, which come sometimes without apparent cause, usually early in the morning, and are apt to be preceded by a sense of euphoria such as is sometimes seen before attacks of epilepsy, migraine, and the like; further, that gout evidently stands in a close relationship of mutual dependence and interchangeability with other neuroses, such as epilepsy, hysteria, asthma, migraine, angina pectoris; that the exciting causes of the acute seizures are often such as depress nervous force, like strong mental and moral excitements, venereal excesses, or sudden shock, without, however, acting directly upon the affected joints; and, finally, that the ability of the nervous system to influence nutrition, as seen in the arthritic complications of certain forms of locomotor ataxia and other diseases, is becoming more and more fully recognized.

Let us now turn to a consideration of the doctrine of lithæmia or suppressed gout, taking as representatives of the positive side of the discussion two of its most earnest supporters in this country, Dr. DaCosta,³ of Philadelphia, and Dr. W. H. Draper, of New York.

Dr. Draper's views were expressed in one of the American Clinical Lectures in 1875, and more recently, and in a modified form, in a paper read before the New York Academy of Medicine in February, 1883.⁴

In the latter paper Dr. Draper refers to the difficulties in the way of the humoral or chemical theory of gout, and admits that it may be primarily a neurosis, and that the over-production of uric acid and its presence in the blood may be only an epi-phenomenon in the disease. His views of the subject of diet have also been modified, but he finds that, in general terms, gouty patients and their descendants have especial difficulty in the digestion of saccharine and farinaceous food. The symptoms described in the first paper as of a lithæmic origin include flatulent and acid dyspepsia, painful and frequent micturition, commonly associated with the presence of uric acid, urates, or oxalates in the urine, neuralgic symptoms of unusual type and without tender points, burning sensations in the palms and soles, numbness of the hands and fore-arms, pain in the region of the tendo-Achillis and the dorsum of the foot, hypochondriasis and hysteria, chronic bronchitis, asthma, conjunctivitis, gastro-intestinal catarrh, aphthous ulcerations in the mouth, obstinate eczematous and erythematous lesions of the skin, the latter sometimes showing themselves in sudden swelling of the eyelids, cheeks, lips, and tongue, together with many other symptoms.

Dr. DaCosta lays especial stress upon vertigo, severe acute periodical headaches of neuralgic type, neuralgia, sometimes bilateral, burning pains in the feet and hands, and also gastralgia, cramps in the legs, sleeplessness, irritability or great depression of spirits, and the like. Other writers have referred to tinnitus aurium (such as Dr. Lyman has described to-night), irritability of the bladder, painful menstruation, etc.

In seeking for the pathology of these symptoms, two questions naturally present themselves:—

(1.) What evidence is there of the existence of an excess of uric acid in the blood; a condition which is assumed without argument by DaCosta, and by Draper in the earlier though not in the later paper?

¹ Brain, 1881, and elsewhere.

² British Medical Journal, 1883.

³ American Journal of Medical Sciences, 1881.

⁴ New York Record, February 24th.

(2.) What other signs have we that would justify us in setting apart these cases as belonging in a group by themselves; or as standing in any definite relation to the gouty diathesis?

Of direct evidence by examinations of the blood none so far as I can learn has been furnished (though Garrod speaks of its great desirability), except that Draper found an excess of uric acid in a case of gonorrhoeal rheumatism which he believed to be of gouty origin. Ball (quoted by Charcot in *Diseases of the Liver*) found uric acid, to be sure, in the blood of a patient suffering from gravel, an observation to which we shall refer again, further on. The only indirect evidence that is offered of the presence of uric acid in the blood consists in the more or less persistent presence in the urine of free uric acid or its salts. This was noted in almost all of DaCosta's cases, and he dwells upon it at some length.

What is the real significance of this sign? Chemically, it certainly indicates nothing more than increased acidity or condensation of the urine, no matter from what cause, which facilitates a precipitation of the uric acid and urates. A real and persistent increase of the total amount of uric acid is very exceptional, and would usually indicate, according to Ralfe, some serious organic or constitutional disorder, such as organic disease of the liver or spleen, phthisis, or cancer. It is not even a regular accompaniment of true gout.

From the clinical stand-point the matter is not quite so simple. So good an observer as Garrod finds from analysis of his numerous cases that gravel and calculus are more prevalent among the descendants of the gouty than among those of the non-gouty, although the gouty patients themselves do not often pass calculi.

The same view is taken by most other writers.¹ The observation of Ball has already been quoted. Charcot (*Diseases of the Liver*) refers to the observations of Rayer as pointing in the same direction, but says that he has himself several times examined the blood and serum from blisters of patients habitually passing uric acid crystals or concretions, without finding a trace of uric acid. On the whole, in spite of the mysterious, but accepted, relationship between gout and gravel, it is impossible to read at all extensively the views of the best authorities without becoming convinced of two facts: first, that to draw any inference from the precipitation of uric acid and urates in the urine this must be proved to be really habitual and not to be accounted for by concentration of the urine due to ingestion of too little fluid, or to temporary indigestion; and second, that even when this is not the case the most that we can say is that we have evidence of a disorder of nutrition which is sometimes associated with lithæmia.

I have in my mind a large family of persons who are, or have been almost all, sufferers from functional nervous disorders, such as insomnia, visceral neuralgias, mental depression, irregularity of the heart, etc. One of them has had what was perhaps gout, though that disease is not known to have been inherited. One member passes uric acid at long intervals for some days at a time, but the one who is the most free from morbid symptoms, and usually in good health, passes urine which habitually deposits urates in considerable quantity.

To turn to the second question, Do the symptoms in the cases that have been called lithæmia present

anything really characteristic, we will not say of lithæmia, but of any classifiable condition, and especially of one related in any way to gout? There is some reason, no doubt, to think that this is the case.

The burning palms and soles, the anomalous and sometimes bilateral neuralgias, the gastralgia and marked tendency to catarrh of the mucous membranes, and other symptoms are frequently said to be met with both in cases of true gout, and on the other hand in cases of another class, the limits of which we are trying to define. This class is believed by excellent observers to be very largely recruited from the families of gouty patients. Two considerations are, however, especially to be borne in mind:—

(1.) That we are only just beginning to learn the range of symptoms due to functional disorders of the nervous system from causes arising within itself or from simple insufficiency of nourishment (so-called *neurasthenia*).

(2.) That it is by no means certain that even in true gout all the symptoms referred to are due to the uric acid in the blood, since many of them may occur, as is pointed out by Ralfe, under any circumstances, such as scurvy, where the relative acidity of the blood is increased in consequence of the quality of the food (withdrawal of alkaline bases, etc.), or in disorders of the digestion, some of these latter being at times dependent on syphilis or other constitutional diseases.²

To return to the first consideration, it is difficult to see why we should in the interests of lithæmia dispossess the doctrine of primary *neurasthenia* of its just claims. There seems no reason why a person should not acquire or inherit, perhaps from a gouty parent, a poorly-working nervous system, and this seems often to happen, since the symptoms referred to may be present without there being any sign in the history of the patient or the condition of the urine to suggest a gouty origin. And if the nervous system can suffer upon its own account, the burden of proof surely rests with those who would refer the results actually observed to the immediate influences of poisoned blood. Whether or not lithæmia is inherited from gouty parents, however, it appears certain that such persons are apt to exhibit themselves, and to transmit to their descendants, strongly-marked neuroses, both general and special.

Finally, how far is it possible to judge from the effects of treatment whether the blood is lithæmic or whether a given set of symptoms are related to true gout? First we must decide in what the appropriate treatment of true gout consists. Is there anything about it which can be called specific? Some years ago this question would, no doubt, have been answered in the affirmative, but the notions with regard to the treatment of gout have of late undergone a considerable change. It has long been known, and the point has been dwelt upon anew at some length by Garrod in his recent paper, that the excretion of uric acid is very little affected by an increase or diminution of albuminous food, and Garrod distinctly states that he believes patients to have suffered in their health from the scanty diet of former times. Dr. Draper, as well as most other writers, now believe that nitrogenous food may be taken pretty freely. It is the hydrocarbons of the food, the sugar and the starch, which are now considered the objectionable portions, but it is

¹ Vide *Nouveau Dict. de Med. et Chir.*, art. *Gravelle*, where this whole question is treated with much fairness.

² I am present trying to ascertain, by a special method, whether the relative acidity of the blood really undergoes much change in such diseases as *dyspepsia*, etc.

very interesting to see the different grounds on which this opinion is maintained. Thus Ralfe, believing that gout is a disease of too great acidity, and analogous to scurvy and rheumatism, thinks the sugar is converted in the intestinal canal to lactic acid, and eventually in the blood to carbonic acid, and that the alkalinity of the fluid is thereby reduced.

Dr. Draper finds that gouty patients as a rule cannot digest sugar or starch easily, and that as a clinical fact these substances do not agree with them, and should be interdicted. Ebstein thinks them objectionable solely because they increase the corpulence of the patients, and thereby indirectly predispose to gout in various ways; an idea which is upheld by some observations in a different field by Fraenkel,¹ namely, that corpulent persons are more likely to suffer from enlargement of the heart through interference with the abdominal circulation. Garrod believes himself to have discovered that it is not sugar in its natural state, but only in a partially fermented state, as in beer, wines, certain fruits, and the like, that is objectionable, perhaps from giving rise to some injurious ferment.

Again, apart from gouty tendencies, there are stomachs enough to which sugar and starch are not indifferent, and it is evident that more extended observations are needed before we can admit that the ability to digest and assimilate hydrocarbonaceous food is enough to distinguish between the possessor of the gouty taint and dyspeptics of other kinds. It is not to be forgotten that while milk diet (which is considered especially suitable for the so-called lithæmic patient) agrees as a rule very well with patients presenting marked nervous symptoms, yet some of them do better on a vegetable and farinaceous diet, without milk or meat. This does not, of course, interfere with the fact that the observations of Dr. Draper and others tending to show that there is a large class of nervous dyspeptics for whom sugar and starch are inadmissible are, if confirmed, of the highest practical importance, and all the more so if these cases can be shown to be generally of gouty origin.

The truth probably is, that the nutrition of patients of this class of so-called lithæmics (in reality perhaps not lithæmic at all) has to be carefully watched, and adjusted to the case in hand.

For my own part I am inclined to think, with Ralfe, that over-feeding, combined with freedom from excitement and care, is often for a time a better plan even than under-feeding with moderate exercise; while the combination of over-feeding and nervous excitement is, perhaps, an especially unfortunate one. Certainly among the multitudes of neurasthenic patients who have improved, temporarily or permanently, under Dr. Weir Mitchell's treatment of over-feeding with rest in bed, there must have been many of the so-called lithæmic class, if this class is anything as numerous as is believed.

Again, the action of saline laxatives and alkalies in gout cannot be regarded as specific. Ebstein discards them altogether, except as a means of correcting the dyspeptic symptoms; other writers regard them as a means of supplying a larger amount of fluid to the system. Voit and others believe that the presence of such salts in the blood increases the metamorphosis of tissue, and thereby the activity of nutrition, by increasing the osmotic circulation. Of course, when it is a question of actually retaining uric acid in solution in

the blood or urine their use may be justified on other grounds.

To conclude, I would express as my provisional opinion that the interests of medical progress would be best served if we avoided for the present the term lithæmia altogether, studying on the one hand, as if *de novo*, the causes which lead to a precipitation of urates in the urine; and observing, on the other, to see whether the nervous symptoms, the dyspepsia, etc., occurring in the descendants of gouty patients, are essentially different from the neurasthenias and dyspepsias in patients who cannot be suspected of the gouty taint. At the same time, whether their explanations are right or wrong, the extremely important service which such observers as Murchison, DaCosta, Draper, and others have done in showing that some close connection exists between disorders of general nutrition and a great variety of symptoms which had hitherto been studied too much in detail alone is worthy of the fullest recognition.

CASE OF DEATH FROM HEART CLOT FOLLOWING ETHERIZATION.²

BY FRANCIS MINOT, M. D.,

Hersey Professor of the Theory and Practice of Physic in Harvard University; Physician to Massachusetts General Hospital.

THE patient was an unmarried lady, forty-five years old, of a nervous temperament, general good health, and rather stout. During the last year the monthly periods, previously regular, had gradually diminished in frequency and amount. The last one occurred early in October. During the past summer she had noticed some shortness of breath, together with an uncomfortable feeling of distention in the abdomen, for which she consulted me October 8d. She had a healthy look, no cough, no fever, the urine was normal, and in the absence of special symptoms no objection was made to her going to Lenox, where she intended to pass some weeks. In consequence of an increase in her discomfort, soon after her arrival in Lenox, she consulted Dr. J. F. A. Adams, of Pittsfield, who found evidence of an effusion in the right chest. She returned to Boston, and on October 15th I punctured the chest between the eighth and ninth ribs, below the angle of the scapula, but failed to get any fluid. The patient was extremely sensitive to pain, and refused to submit to a second puncture without being etherized. After a delay occasioned by the necessity of sending for the ether, she was put under its influence, the trocar was pushed through the next interspace above, and nearly two quarts of serum, strongly tinged with blood, were withdrawn. Nothing unusual in reference to the etherization occurred, and the patient was relieved by the operation. Strong tincture of iodine and blisters were applied to the back, and the iodide of potassium was given internally. The general condition was good, the temperature and pulse were normal, and the patient drove out daily in good weather. After a few days, dullness and faintness of the respiratory murmur were observed in the lower part of the right chest, but in the upper two thirds the condition was normal.

November 2d the patient went to Falmouth, where she spent twelve days, during the greater part of which she was out of doors taking long drives, walking a

² Read before the Boston Society for Medical Improvement, November 12, 1883.

¹ Zeitschrift der klin. Med., 4ter Band.

little, and sitting on the piazza, the weather being very mild. On her return to town she complained of the same symptoms as before, but especially of the feeling of distention of the abdomen, and imagined she might have a tumor there. Examination of the abdomen revealed nothing abnormal, unless a considerable amount of flatulence; there was no ascites, and no tumor could be felt. A digital rectal examination was made at the patient's request. The uterus was easily felt, apparently of normal size, and no tumor was detected in the pelvis. The temperature and pulse were normal. The urine, examined November 15th, contained a large amount of urates, but no albumen. Its gravity was 1015. The appetite was fair. There was a large amount of fluid in the right chest, and it was arranged that a second aspiration should be done on the next day, November 16th. On that morning the patient seemed to be in her usual health. She evidently dreaded the operation, but made no objection to it. As on the previous occasion she lay upon a sofa, inclined towards the left side, the shoulders being considerably raised by pillows. She was etherized without any special symptom; but after about half a pint of reddish fluid was withdrawn from the chest it was noticed that she became very livid, and that the breathing was irregular and gasping. She had vomited a little fluid once during the etherization, and it was thought that some of the contents of the stomach might have passed into the larynx. (She had taken no food except a little beef tea and some coffee since the preceding evening.) The canula was immediately withdrawn from the chest. The patient's jaws were separated. Cold water was dashed on the face, ammonia applied to the nostrils, etc., and in about fifteen minutes she began to breathe freely, though somewhat rapidly, and the livid color of the face nearly disappeared. Two hours afterwards she was sleeping quietly, and the color was nearly natural; but an hour and a half later the dyspnoea and lividity returned. The respiration became rapid, its rate being about 46, and the pulse 144 in the minute. There was a fine moist râle throughout the left chest. The heart-sounds were distinct, but faint. There was no valvular murmur. The face and hands became very dusky, and the patient was evidently in a state of asphyxia. She was conscious, was aware of her danger, and made some requests to her family in relation to the event of her death. A large sinapism was applied to the left chest. Brandy, ammonia, digitalis, and pilocarpine were injected subcutaneously, and champagne was given by the mouth, but she expired without struggle eight hours after the beginning of the etherization.

An autopsy was made November 17th by Professor Fitz, who has furnished the following report: Body warm. Face and neck, especially the latter, livid. Yellow, frothy fluid escaping from the mouth. Abdomen distended. Head not opened. Fat tissue throughout the body excessive, the subcutaneous fat of the abdominal wall being at least an inch and a half in thickness. Pericardium contained no excess of fluid. Both sides of heart, especially the right, distended with blood. On opening the right ventricle an elongated, cylindrical, grayish-yellow thrombus was found, nearly two inches in length, and as large round as the tip of the little finger. It extended from about two thirds of an inch below the origin of the pulmonary artery into the latter, and was loosely united to the valve. Its surface in general was smooth, though cor-

rugated at the uppermost part, and its consistency was firm except at the posterior portion, where it was soft, and the color a reddish gray. Soft, clotted, red blood was loosely attached to its surface, and a firmer dark-red clot, also attached, filled the ventricular cavity and distended the auricle. The thrombus was continued into the pulmonary arteries as far as their third bifurcation, at least, by small, thin, and soft dark-red clots. The left side of the heart contained liquid and freshly-clotted blood. The valves showed no abnormal appearance. The heart, as a whole, was small; the muscular substance of the right ventricle was excessively infiltrated with fat, which in many places wholly replaced muscle. For the most part the muscle fibres were free from evidence of degeneration, although they were occasionally found in a granular condition. The myocardium of the left ventricle presented no abnormal appearance. There was no increase of sub-endocardial fat, nor any marked increase of that beneath the pericardium. The right pleural cavity contained nearly two quarts of watery fluid stained with blood; the lung was moderately retracted, free from adhesions, and an incision showed nothing abnormal excepting a dryness of the upper, and a moderate oedema of the lower, lobe; as a whole it was anæmic, with an absence of air throughout the posterior and lower portions. The parietal, especially diaphragmatic, pleura, as well as that covering the lung, showed numerous small, gray nodules and plates of new formation, from which an opaque juice of creamy consistency escaped on pressure. The left pleural cavity contained a few ounces of fluid, and the pleural surface showed but a few of the nodules just described. The left lung was moderately injected and oedematous, with viscid yellow drops exuding from the cut bronchi.

The abdominal cavity contained several ounces of opaque pink fluid. The peritonæum, especially of the pelvis and of the right half of the diaphragm, bore nodules and patches similar to those found in the right pleural cavity; they were also found in the muscular portions of the right diaphragm. The omentum was transformed into a dense, gray, cylindrical mass, in intimate contact with the transverse colon. Spleen, kidneys, and liver showed nothing abnormal, with the exception of an unusual quantity of blood. Gall-bladder firmly contracted about several calculi imbedded in mucus; the mucous membrane appeared normal, the hepatic and common ducts free. Stomach distended with gas; its mucous membrane showed no abnormal appearance.

External examination of the intestine showed nothing abnormal. The pelvic organs were adherent to the wall. Bladder normal. Uterus large; its mucous membrane besmeared with a viscid, opaque, white fluid. An intramural fibro-myoma, as large as a small peach, projected from the fundus. Both ovaries converted into multilocular cystic tumors, nearly as large as a hen's egg; the walls of the cysts smooth; the contents thin and watery, or thick, yellow, and red. The altered ovaries, tubes, and broad ligaments firmly united together, and incrustated with tumors like those previously described. The structure of these tumors was everywhere the same, an alveolar stroma, containing small polymorphic cells of an epithelial type. There was no odor of ether about the body.

Summary. Cancerous peritonitis and pleurisy; fatty infiltration and fresh thrombosis of right ventricle; multilocular ovarian cysts; uterine fibroid; biliary calculi, with atrophied gall-bladder.

Death consequent on the inhalation of ether is so rare an event that every case should, if possible, be reported in detail, and be subjected to the closest scrutiny, in order that by comparing such cases together we may possibly be able to discover the cause of the fatal event, and perhaps be able to avert it in future. In the present instance it is evident that death was caused by asphyxia, and not, as in chloroform narcosis, by paralysis of the heart. The patient lived several hours after the first alarming symptoms; she was conscious, and was able to speak. There was no obstruction in the air passages. A thrombus had formed in the right ventricle of the heart, producing in the first instance embarrassment of the pulmonary circulation, and after its size was increased by gradual accretion of coagula, finally stopping it altogether. How can we account for the formation of the clot? The patient was apparently in fair health, but the extremely fatty condition of the walls of the right ventricle of the heart, in addition to the presence of a large effusion in the right pleural cavity, doubtless weakened the heart's action, which effect was further increased by the disturbing action of the anæsthetic on the respiration. This condition of things was perhaps aggravated by the inclination of the patient toward the left side, which allowed the weight of the fluid in the right pleura to press somewhat upon the heart and the left lung. How far the cancerous cachexia of the patient tended to favor coagulation of the blood I have no means of knowing. At all events the situation seemed exactly the same as at the time of the previous operation, when no untoward event occurred; nor did it differ essentially from that in many cases of etherization of daily occurrence. The thrombus was not the result of removal of fluid from the chest, as scarcely eight ounces had been withdrawn.

Some other points of interest in this case may be briefly alluded to: The discovery at the autopsy of cancerous disease in the thoracic and abdominal cavities was not wholly unexpected on account of the character of the fluid withdrawn from the chest. Dr. Bowditch long ago pointed out that the presence of bloody serum in that cavity is strongly diagnostic of cancer of the lung and pleura; but in the absence of any other evidence of cancer I hoped that the blood might in this case have been caused by wounding the lung with the trocar at the time of the first operation, although the color of the fluid was uniform, and there were no clots. Though I believe that Dr. Bowditch's rule has few exceptions, yet one such has occurred in my practice. In August, 1879, I removed from the chest of a gentleman of this city a quantity of fluid which resembled exactly that obtained in the present case. The patient recovered, and is now alive and well. On the other hand I have performed paracentesis of the left chest five times within the last few weeks in the case of a lady who has had both breasts removed for cancer; but though it seems highly probable that the effusion in this latter case is the effect of a cancerous invasion of the pleura or lung, the fluid withdrawn has each time been clear and perfectly free from blood. In the case now reported the aspect of the patient was that of a person in perfect health. So far from being emaciated, she was unusually plump; there was no pallor, and she complained of no pain, though there was a feeling of discomfort, or, as she expressed it, of "tightness," in the abdomen. The absence of symptoms of cancer may be explained by the fact that the

malignant disease had not yet invaded the structure of any vital organ.

That the patient had experienced no symptoms relating to the menstrual function is remarkable, considering that both ovaries were apparently destroyed by cystic disease; for the diminishing frequency of the periods must be regarded as normal at her age. The uterine fibroid was so situated as to be liable to give rise to no hæmorrhage; and it was not large enough to cause inconvenience by its bulk.

So far as we are justified in drawing conclusions from a single observation, we may learn from the above case: (1.) That etherization is not altogether safe for a patient with a large effusion in the chest, and should not be employed if it can be avoided. (2.) That when employed, unusual care should be taken to prevent accidents, and especially that the patient should be inclined towards the same side with the effusion. The case also confirms Dr. Bowditch's law, that the presence of blood in the fluid removed from the chest is a strong presumption in favor of cancer of the lung or pleura, or both.

ENTERIC PARAPLEGIA.¹

BY ROBERTS BARTHOLOW, M. D., LL. D.,

Professor of Materia Medica and General Therapeutics in the Jefferson Medical College, Philadelphia.

By the term enteric paraplegia I intend to express the conception of a spinal paralysis, produced by an intestinal disorder. It is a truly reflex paralysis. The fact of the existence of such a malady is denied by many, and indeed most of the reported examples will not bear careful inspection, for it will be found, as I shall show, that they are really cases of ascending neuritis. Eliminating such from the examples of true reflex paraplegia to be found recorded, I intend to place the latter in a special group composed of cases presenting the symptoms of an enteric disease, during the course of which a motor and sensory paraplegia manifests itself, and pursues a course obviously dependent on the original lesions. The cases I have lately seen occurred in men over sixty years of age, and each one presented a morbid complexus so distinctive and uniform as to entitle it to be regarded a substantive affection — a pathological entity. Although such cases have been described as examples of reflex paralysis, they have not been adequately differentiated from others similarly classified but of different nature.

Before attempting the task of analysis and differentiation, I must give a brief outline of three cases, the most recent which have come under my observation.

CASE I. Mr. R., aged sixty-four, merchant and banker, of very vigorous and robust frame, rather spare and bony in outline, but capable of great endurance, called on me a year ago, amongst other physicians of this city, for relief to an obstinate bowel affection. His story was this: for a year or more previously he had suffered with intestinal indigestion, colic pains, flatulence, and considerable depression of spirits. Soon after these symptoms were experienced he began to have pain in the back, with more or less band-like constriction of the abdomen, a feeling of numbness in the feet and legs, a strong sense of fatigue in the inferior extremities, followed by weakness and awkwardness of move-

¹ Proceedings of the College of Physicians of Philadelphia. Read November 7, 1883.

ments in walking, obstinate constipation, and slowness in the emission of urine. For the relief of these alarming symptoms he consulted an eminent practitioner of this city, who diagnosticated myelitis and advised cups, the moxa, and a pill which probably contained ergot. Without using any of the local applications, Mr. R. took the pills, which had a favorable effect in relieving the flatulence and constipation, but presently dysenteric attacks supervened, and then a remarkable change ensued in the spinal symptoms. Up to this period the paraplegia had steadily increased, and walking had become exceedingly difficult, but the change in the condition of the intestine effected a revolution in the state of the spinal functions, and in the course of a few weeks all the paralytic symptoms had disappeared. Still troubled with intestinal indigestion, Mr. R. finally consulted me amongst others, when I learned the details of the case just given. Very recently I have heard that Mr. R. continues free from the spinal symptoms, and has in the main got rid of his intestinal disorder.

CASE II. Mr. P., a tall, thin, but hardy Quaker farmer, aged seventy-two. I saw the patient at his home near Delta, York County, this State, in consultation with Dr. Hickman, a very intelligent practitioner living there. I learned that the patient some ten years before had experienced a similar attack, but had recovered rather suddenly under the influence of remedies which were then prescribed. For some years he remained comparatively free from disorders of digestion. The present attack came on during the past winter; at first there appeared a very considerable disturbance of digestion,—acidity, pyrosis, flatulence, and colic pains. The distress was increased by taking food, and apparently attained its maximum when the alimentary materials entered the intestines. In fact the symptoms of intestinal indigestion were the most pronounced throughout, and to these were added obstinate constipation, the stool consisting of balls united by masses of mucus or coated with the same. Very soon after the gastro-intestinal catarrh was established Mr. P. began to experience numbness of the feet and legs, and an increasing difficulty of locomotion.

At the time of my visit with Dr. Hickman the patient was nearly entirely disabled. The history of very severe and continuous digestive troubles was repeated. I will, therefore, to occupy as little time as possible, pass on to the objective examination of the paraplegia.

He could not stand without assistance; there was an extreme degree of ataxia; the muscles were so weak that his utmost efforts could not at all hinder slight movement of extension when the legs were flexed on the thigh; the tactile sense was so lowered that the points of the aesthesiometer could not be felt at all; the muscles responded feebly to an induction current; the emission of urine was very slow, and there was much dribbling afterward, and the bowels were extremely sluggish. There was a feeble knee-jerk.

With attention directed entirely to the digestive trouble, beginning with an exclusive milk diet, in two weeks a marked improvement was manifest in all the symptoms, the paraplegia disappearing. In a letter recently received from Dr. Hickman I learn that after a period of very great improvement Mr. P. began to decline in strength, owing to failure of the functions concerned in nutrition.

CASE III. Mr. McK., of Clearfield County, about

sixty years of age, has had for many years frequent attacks of sick headache. Within the past year pronounced symptoms of intestinal indigestion, pain of a colicky character, flatulence, and irregular action of the bowels, etc., have come on, but the symptom which has caused the greatest apprehension, and on account of which more especially he has called on me, is an increasing numbness, with some diminution of power, of the inferior extremities. The tactile, pain, and temperature senses are not abolished, only slightly impaired, and the tendon reflex is unaffected. A feeling of fatigue, of weight and heaviness, is felt in the legs, but locomotion is not as yet much affected. I await further developments in the symptoms referable to the nervous system, but meanwhile treatment is directed to the gastro-intestinal disorder.

Cases similar to those which I have thus briefly outlined have been recorded by various observers. An admirable example, and one of the first of its kind, was narrated by that eminent clinician, Graves, of Dublin.¹ In this case extreme gastric disturbance, with less important intestinal, came on in distinct paroxysms, varying in duration from several days to two or three weeks, and accompanied by complete motor paraplegia. For a time entire recovery took place, the paralysis disappearing with the cessation of the other symptoms. Finally the attacks grew so frequent as to be almost continuous, and death ensued from exhaustion. The minutest examination failed to disclose a lesion in any organ of the body. With the advance in our means of investigating morbid states such cases of presumed functional disease of the nervous system are becoming more and more rare. That there is a condition of reflex paraplegia, due to anæmia of the cord, is a postulate I expect to maintain. That there is, however, a so-called reflex paraplegia connected with diseases of the gastro-intestinal and genito-urinary tracts which is not truly reflex is another postulate that I believe to be susceptible of demonstration.

There was a period, in England more especially, when the notion of reflex paraplegia secondary to intestinal, renal, and genital disease, was widely entertained. The cases first reported by Stanley,² Brodie,³ Stokes,⁴ Graves, and others, were supplemented by the striking narratives of Gull.⁵ Then Brown-Séquard⁶ gave a scientific explanation of the mechanism, referring the paralysis to vaso-motor action. It must be admitted, nevertheless, that the doctrine of a reflex paralysis has not maintained the position it once had. In no modern work is the subject treated with the extent and gravity befitting an important disease.

The two postulates I purpose to sustain are:—

- (1.) That there is a reflex paraplegia due to a functional disturbance of the intestine, enteric paraplegia.
- (2.) That there is a paraplegia having its initial seat in the end organs of the nerves distributed to the mucous membrane, thence ascending to the cord by a progressive neuritis.

As respects the first postulate, the cases I have narrated, and many others on record, demonstrate a causal connection between the enteric disorder and the spinal. That the paraplegia is functional is proved by its

prompt cessation when the cause is removed. One of the means of determining whether a given paraplegia is due to a myelitis or to mere anæmia — that is, functional — is the subcutaneous injection of strychnine. At a late meeting of the American Neurological Association Dr. Jewell, of Chicago, recounted his experiences with considerable doses of strychnine in cases of paraplegia which improved so remarkably that they must have belonged to the merely functional group. It is in a high degree probable that cases of merely reflex paraplegia, — of enteric paraplegia, — especially as they occur in aged subjects, are relatively frequent, and happen from a degree of intestinal disturbance that seems a mere accident of the morbid complexus.

What is the mechanism? We are helped in our consideration of this question by physiological data. Kussmaul and Tenner (quoted by Erb) have shown that sufficient loss of blood will cause paraplegia. Tying the abdominal aorta, and its obstruction by disease, of which Gull¹ has given a striking example, embolic blocking of the spinal vessels, as Panum² has experimentally demonstrated, and large uterine hæmorrhage, as Moutard-Martin³ has shown, have alike stopped the spinal cord functioning. In other words, an insufficient blood supply — an anæmia — is a cause of paraplegia. Brown-Séquard, in his Lectures, published in 1861, maintained the thesis that a strong contraction of the vessels of the cord induced by reflex stimulation is the essential condition in reflex paraplegia. We should not lose sight in this connection of the degree of stimulation necessary. A moderate degree of intestinal irritation suffices, for the law of reflex contraction of the vaso-motor fibres may be formulated thus: irritation of the end organs of the sensory nerves, not too violent and long continued, stimulates the vaso-motor centre in the medulla, and causes a general contraction of the arterioles; but excessive and protracted irritation depresses the vaso-motor centre and relaxes the vessels. It seems probable that an ordinary intestinal indigestion, and the stretching of the nerve fibres produced by retained gas, is a degree of irritation sufficient to produce the supposed effect. To the further elucidation of the mechanism of enteric paraplegia it is necessary to recall the fact that the blood pressure in the vessels of the intra-abdominal organs rises and falls within considerable limits in quite an independent manner, controlled, doubtless, by the same ganglia that regulate the calibre of the intra-spinal blood-vessels.

The circulation within the spinal canal is peculiar, in that the veins bear such a disproportionate volume to the arteries, and that the whole vascular supply is in a certain sense a diverticulum. Atheroma of the vessels will contribute to the result of reflex irritation, and hence it is that paraplegia has resulted from endarteritis of the spinal vessels.

The second postulate is that the paraplegia, which succeeds to certain cases of enteric, renal, or genital disease, is due to an ascending neuritis. Chronic dysentery, pyelitis, and vesical catarrh are affections during the course of which the spinal cord has become diseased. Lesions of continuity involving the terminal nerves in structural changes are necessary to the production of this effect. The part which ascending neuritis may play in causing anatomical alterations of the spinal cord is exhaustively shown by Friedreich in

his monumental work on progressive muscular atrophy.⁴ Whether we accept his conclusions or deny them, we cannot withhold the full measure of admiration for his labors. Starting with the theory of an intramuscular neuritis, Friedreich holds that by an extension of this affection upwards the cord is ultimately reached, and the changes belonging to progressive muscular atrophy are wrought. The intramuscular neuritis admitted, the rest may easily follow. Under the term "Chronic Ascending Neuritis," Dumenil has described the changes in injured nerves which, caused by trauma, proceed from the point of injury up to and involve the cord. Vulpian has especially demonstrated the modifications produced in the spinal cord, by the section of a principal nerve in a member, usually the sciatic.⁵ The nerves of a limb amputated, as Dickinson has especially shown, undergo degenerative atrophy, and that part of the spinal cord in anatomical connection therewith also atrophies. Many other observations might be quoted, but these will suffice to show how changes in the cord follow injuries to peripheral nerves.

In paraplegia secondary to ulceration of the mucous membrane we can readily, I think, conceive of a lesion of the peripheral nerves and an ascending neuritis to which the succeeding changes are due. It follows that such cases require a very different prognosis from those of simple reflex paralysis. The course and termination of the latter are affected by the causal lesions, whilst the former pursue a steadily unfavorable direction from the beginning of the spinal symptoms. The differentiation of reflex from secondary paraplegia is made by attention to the following points: —

Reflex paraplegia is sudden in its onset, or, at least, develops quickly; secondary paraplegia is gradual in its evolution; the former is soon complete in all points of its symptomatology; the latter attacks one spinal function at a time. Reflex paraplegia follows the fortunes of the producing malady; secondary paraplegia pursues an independent course, and when the alterations begin in the spinal elements they proceed in their own way, just as after amputation of a limb the changes in the cord go on in the associated nerve fibres, or, as in Landry's ascending paralysis, the lesions proceed by contiguity of tissue. Reflex paraplegia, of and by itself, never proves fatal, nor does it inflict permanent damage; secondary paraplegia may be the cause of death, and, if not fatal, effects lasting mischief.

To this view of reflex paraplegia it may be objected that extreme variations in the vascular supply must ultimately lead to structural changes. This is certainly possible, but the spinal, like the cerebral, circulation is arranged to permit considerable variations in the amount of blood.

It remains to explain, if an explanation be possible, why intestinal or renal lesions may in one case produce a merely reflex disturbance, and in another, set up an ascending neuritis. There are, probably, two reasons: (1) the depth and extent of the peripheric lesions; (2) an inherent susceptibility to degenerative changes in the nervous elements. The first to me has profound significance, and I have already alluded to it. A degree of peripheric irritation not too great will merely stimulate the vaso-motor centres, and cause anæmia of the cord by tonic contraction of its vessels,

but when the lesions of the mucous membrane are of a destructive kind, depression of the trophic centres, as well as of the vaso-motor, ensues. That there is a neuropathic type of constitution, in which the nerve tissues are peculiarly prone to take on morbid changes, is an indisputable fact. When the two influences coincide the result is not doubtful.

I must, then, conclude, that there is a malady which may properly be entitled *Euteric Paraplegia*.

Reports of Societies.

PROCEEDINGS OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.

ALBERT N. BLODGETT, M. D., SECRETARY.

NOVEMBER 14, 1883. Meeting called to order at eight o'clock by DR. GEORGE B. SHATTUCK, chairman.

MEDICAL TRAMPS.

DR. H. I. BOWDITCH requested the privilege of occupying a few moments for the purpose of warning the profession against a band of medical tramps which at present infests Boston and its suburbs and by every expedient seeks to obtain pecuniary aid from physicians. One of these impostors has suffered an amputation of the thigh, wears an artificial limb, professes to be a graduate of Harvard and the son of a physician, and presents plausible testimonials recommending him to the profession. The letters of commendation were found by Dr. Bowditch to be forgeries, and the man himself is a swindler. Another member of this band of conspirators is a young man who is elaborately dressed and makes a favorable appearance, and whose habit is to call at the physician's house when the doctor is away. He represents himself to be the son of a celebrated physician of New York who is a very intimate friend of the physician at whose door the young man is standing. He further states that he has been robbed of all his money and desires to borrow a sum, generally from three to five dollars, to aid him in reaching his home. Upon being informed that the doctor is not at home his eyes fill with tears and he appears to be in great distress of mind, and at length endeavors to borrow the sum required of the person who has come to the door. If he does not succeed in this ruse, he asks the time at which the doctor will return, and is very particular *not* to return at that time. Another is a man of swarthy complexion, who pretends to be from India, but is probably an arrant cheat.

The regular business of the evening was then taken up. The first matter was the election of a chairman for the ensuing year, the present incumbent, Dr. G. B. Shattuck, who has filled this office for two years, having positively declined a reelection. On motion of Dr. R. M. HODGES, seconded by Dr. A. L. MASON, the name of Dr. R. T. Edes was proposed, and he was unanimously elected. As Dr. Edes was not present, the Secretary was directed to acquaint him with the action of the Section.

DR. G. H. LYMAN then presented the first paper of the evening, entitled

TINNITUS AURIUM AND VERTIGO AS PROMINENT SYMPTOMS OF LITHÆMIA.¹

This was followed by a paper presented by DR. J. J. PUTNAM, entitled

RECENT VIEWS CONCERNING THE DIAGNOSIS AND TREATMENT OF LITHÆMIA.²

The CHAIRMAN alluded to the thoroughness with which the ground was covered by the two readers, and hoped that the discussion of the subject would be full and complete. The subject was then placed before the meeting.

DR. S. G. WEBBER said that he had been very deeply interested in both the papers, but wished that in addition to the opinions of so many distinguished authors Dr. Putnam had given us his own views upon lithæmia at greater length. From his review we must conclude that we really know very little upon the subject; even observers who have devoted much time to the study of the questions involved, have changed their views within the last few years, and now hold opinions quite different or the reverse of their former opinions.

Two symptoms have not been mentioned in these papers, which are not so frequent, perhaps, as the others, but are yet of interest, — irritability of temper, or a change of disposition; this may be only an accidental coincidence depending in part upon the annoyance and discomfort caused by the other symptoms, perhaps, however, it may be due to the deficient nutrition of the brain. These patients are often much more disturbed at certain times in the day than at others, are excitable, and sometimes violent. Another symptom is temporary deafness, which may last only a few hours.

The diagnosis between lithæmia and other nervous affections is by no means always easy. Two conditions or diseases may be thought to be present, namely tumor of the brain and epilepsy, when there is only lithæmia. A patient with headache, tinnitus, vertigo, change of disposition and languor, may be suspected of having a tumor; even a careful examination may not satisfactorily clear up the doubt, and it would be necessary to wait for time to show the truth by the development of other symptoms, or by the recovery of the patient.

Vertigo even without loss of consciousness raises a suspicion of epilepsy; when several attacks occur near each other, and then again after a long interval another series of attacks, the resemblance is quite close. As a rule, in lithæmia consciousness is not lost; in epilepsy consciousness is usually lost in some of the attacks, though exceptionally these partial attacks may precede by several months or years the fully developed *grand mal*. In lithæmic vertigo the bromides, which usually lessen the number and severity of the epileptic attacks, have little or no influence for good. Yet it is necessary to guard against an apparent benefit which would be deceptive; if the bromides were given at about the time of a natural remission in the symptoms the drug might seem to be of benefit. Time would show the error.

We probably need to pay more attention to the character of the urine in all doubtful cases.

DR. DAVID HUNT remarked that this discussion has suggested the relation of the science of medicine to the art of medicine; our history proves that attempts to

¹ See page 553 of this number of the JOURNAL.

² See page 556 of this number of the JOURNAL.

use pure hypotheses as foundations upon which to build methods of practice have obstructed the progress of the art of medicine; in the present instance we have no definite knowledge of the formation of urea and of the conditions in which it exists in the blood; such being the case, I am very skeptical as to the advantage of adopting the name "lithæmia" as descriptive of a morbid condition for which a special therapeutics is adopted.

If lithæmia is to be considered as a form of larvaceous gout we must also acknowledge that since Sydenham's day we have added nothing to his description of gout but the name "urea"; yet he has said nothing of tinnitus aurium as a symptom of this or of any other form of the disorder; it is suggestive to observe how little such a clinical artist as Trousseau has been able to add to Sydenham's description, and that he, too, has had nothing to say of tinnitus; as far as therapeutics are concerned it is noticeable also that the alkaline cathartics, so advantageously employed in lithæmia, are just the remedies which Trousseau has warned against as so dangerous in larvaceous gout.

If the blood-poisoning in this condition is to be accepted as the specific cause of the irritation of the auditory nerve, is it not surprising that we hear so little of tinnitus in Bright's disease, excepting in those cases where we get direct, local causes in the catarrhal affections which accompany it? We know that anæmia causes irritability of this and other nerves; we know that closure of the Eustachian tubes, spasm of the tensor tympani and stapedius muscles, and various disorders, by direct and by reflex action upon the rich nerve supply of the middle ear, cause this symptom; having founded our knowledge upon so much of fact, we hold that it is not good practice to introduce into this department of knowledge a hypothesis founded not only upon no certain knowledge, but also upon no well-known analogy. Aurists, in the vast majority of cases of persistent tinnitus, are able to demonstrate the cause in some local disease; other objective causes no doubt remain to be discovered, but a theory of "lithæmia" is in no way calculated to aid the search. Let us recall the time when every "blepharitis" was "scrofulous," or "gouty," or something else, and then think of the condition to-day, when, as every oculist knows, nine tenths of the cases of blepharitis are caused by the lack of proper glasses, and ask ourselves if these specious but baseless hypotheses have ever advanced the art of medicine. As long as they kept us from the path which Donders, Von Graefe, and Helmholtz have followed, they not only kept us from the best in art, but they constantly opposed the application of the methods of science; so in this matter a "lithæmic" tinnitus or vertigo, without adding anything to our practical success, will stand in the way of that careful objective study by which Hebra has made modern dermatology what it is, and to which modern science is continually directing the student of medicine.

DR. C. J. BLAKE thought that tinnitus, like pain, might be regarded as a physical conscience, too valuable as a symptom to be ignored or put aside with superficial investigation, and that in weighing it as a symptom, due regard should be had to the character of the tinnitus and its origin. Subjective noises in the ear may be for instance either of extrinsic or intrinsic origin: under the former head being included noises resulting from the movements of foreign bodies in the external canal, as of a hair impinging upon the membrana tympani, movement of fluid in the middle ear,

sounds resulting from contraction of the muscles, changes in tension of the membrana tympani, and in the condition of the Eustachian tube, and the like; while under the head of intrinsic causes may be classed, for the purpose of distinction, the various circulatory murmurs and other sounds, more distinctly musical as a rule, which indicate some irritation of the auditory nerve.

In regard to the cases described by Dr. Lyman the intrinsic cause of the tinnitus may be masked by the existence of a thickening of the mucous membrane of the middle ear, in itself sufficient apparently to account for the subjective sound, in this case a circulatory murmur, the same obstruction in the middle ear which prevents sound from passing inward preventing this sound from passing outward; for, as Dr. Draper says, in cases of gouty habit there is both an irritation and inflammation of the mucous membrane and a vessel dilatation; the former favors a progressive thickening of the mucous membrane of the middle ear, the latter, when it occurs in the ear, furnishes an increased circulatory murmur.

To treat the local trouble of the middle ear^{only}, under such circumstances is of course a mistake; it is equally a mistake to leave the ear out of consideration altogether and to refer the aural symptom under consideration to general causes alone.

DR. R. H. FITZ said that he agreed entirely with the views presented by Dr. Putnam, which contain the opinions of the most recent writers upon lithæmia in its various forms and phases. It is still true, however, as Dr. Hunt has stated, that we as yet know but very little about the essential character of the disease, of which we are obliged to judge from a complex and often a contradictory array of symptoms. Most cases in actual practice are best treated by attention to the underlying dyspepsia. In that variety of this disease represented by neurasthenia the patients sometimes lose flesh and grow worse at the same time, though this is far from being the rule. In the dietary of lithæmia each individual patient must find out by experiment and experience what things he can take, and what he must avoid.

DR. C. F. FOLSOM stated that he had seen such cases, and that he had arrived at conclusions regarding them similar to those of Dr. Putnam. Dr. Folsom does not feel at all sure of the pathology of these cases, but treats them all on the same general principle. He mentioned a case occurring in a lady in which tinnitus had been the prominent symptom, and had subsided under tonic treatment. During some years no symptoms of lithæmia were observed, when, suddenly, last summer, an attack of gout supervened.

DR. G. L. WALTON remarked that in many instances there is no ascertainable objective cause for subjective sensations of hearing. The amount of distress occasioned by the noise in the ear varies greatly according to the momentary state of mind which the patient may for the time be in, so that a uniform degree of irritation will awaken a very variable and uncertain amount of reaction or response, sometimes to a degree in no way corresponding to the intensity of the cause, and frequently to a degree far in excess of the normal reaction to the cause. We see this illustrated in the ordinary events of daily practice, as when, for example, one patient cannot obtain sleep if a clock be ticking in the room, while another patient may find the silence of the night oppressive from it,

unbroken stillness, and may absolutely require the aid and companionship of a noisy mechanical device of wheels and bell, weight and pendulum, in order to procure quiet and refreshing slumber. The symptoms at different times are variable while the cause may be the same; there is a change in the amount of reaction from a uniform degree of stimulation. It is very probable that the functions of the nerve centres become disordered from anæmia due to malnutrition.

DR. HUNT thought that not half the cases of tinnitus could be explained on the hypothesis of a functional disorder of the nerve centres from excess of uric acid in the blood. All subjective noises are produced by an irritation of some or of all the fibres of the auditory nerve in some part of its course. It is not necessary to seize upon the idea of a lithæmic excess to account for this symptom, as we may be thus diverted from the real object of our study, which may be of an entirely different character.

DR. LYMAN agreed with the main portion of the discussion, and freely admitted that a large proportion of the cases of tinnitus may be accounted for by tangible and ascertainable disease, but a considerable number are not due to such causation. The question is, "What causes the tinnitus in these cases?" It may be due to the blood. It is known that a suitable nutrition, and the vaso-motor system both have much to do with subjective symptoms of all kinds. Under these conditions the heart may be deranged. This symptom is present in a group of cases which represents a large class of patients with subjective auditory symptoms, and particularly tinnitus. The treatment advocated in the paper read before this meeting relieves these symptoms, and we naturally deduce the theory of blood change. Many opposing hypotheses have been brought forward in relation to these well-known symptoms, and we might well become bewildered and skeptical of any knowledge upon the subject. In the cases here presented the subjective phenomena were marked, and in all quickly yielded to the same treatment, and the treatment may be claimed as a truly curative one in tinnitus and vertigo.

DR. G. B. SHATTUCK said that he had intended calling attention to the result of the treatment as supporting the diagnosis in the cases reported. Many cases, however, are observed in which tinnitus and vertigo occur, one or both, and which may undoubtedly be regarded simply as cases of malnutrition. When we attempt to group all these cases under the head of lithæmia we should not allow the name to deceive us as to the extent of our knowledge in regard to them.

PROCEEDINGS OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. SUCKINGHAM, M. D., SECRETARY.

NOVEMBER 26, 1883. DR. CHARLES D. HOMANS presided.

DR. JOHN HOMANS reported a case of

MYXO-SARCOMA OF THE LEFT KIDNEY. REMOVAL, of which the following is an abstract:—

The patient was a fisherman, twenty-nine years old. He had, without known cause, been losing weight for about two years. The first thing noticed had been pain in the small of the back. This afterward ex-

tended to between the shoulders, and was followed in six months by bloody urine, which last recurred at irregular intervals. There was a hard flat tumor moving with respiration and extending from the left iliac fossa to the splenic region beneath the ribs and across the abdomen nearly to the umbilicus. The urine, examined by Dr. Cutler, showed no increase in white blood corpuscles, and no albumen, other than was accounted for by the blood. The urethra had been plugged by clot, making the use of the catheter necessary. The absence of calculus in the bladder was shown by sounding. The bowels were regular. The man was unable to work, because of the increased pain caused by it, and was anxious for an operation, and willing to run the risk. Of the consultants who saw the case, all but one believed it to be a tumor of the kidney. He thought it was one of the spleen. On November 24th the tumor, which was shown to the Society and which weighed four pounds, was removed under carbolic spray, an incision being made along the left linea semilunaris from the cartilage of the ninth rib to a point in front of the anterior superior spinous process of the ileum, and the opening enlarged by cutting backward toward the loin four inches. The descending colon, which was spread to twice its width, was slightly wounded in the operation and sewn up with the continuous suture. Another incision through the peritonæum exposed the tumor, which extended up under the diaphragm, encroaching on the thorax. Not being adherent, it was peeled out, both its ends were raised, and the renal vessels and ureter were first clamped, and then tied with silk. The room of the tumor was plugged with sponges while the abdomen was examined for clot, and then an incision was made through the quadratus lumborum to admit a drainage tube. After the operation a half drachm of laudanum and a half ounce of brandy were given in an enema. On the evening of the operation the pulse was 118, the temperature 102.2° F., and the respiration 35.

There seems no reason why the patient should not have lived, had the other kidney done its work. The urine varied from chocolate to deep turbid red, and was diminished. In the last twenty-four hours there were less than four ounces, the quantity having been five and a half ounces in the previous twenty-four hours. The patient died at two o'clock to-day, the temperature having been 100° F., pulse 120, respiration 32.

In answer to a question by Dr. Lyman as to cerebral symptoms, Dr. Homans said that the patient was calm or perhaps stupefied and slept much, but that there was no convulsion and no headache.

The question of carbolic poisoning having been raised, Dr. Fitz inquired as to the urine. Dr. Homans said that it was not green, and that that which he saw after the operation did not contain blood. To a question of Dr. Bradford he stated that the temperature did not go above 100.3° F., nor below 99° F.

DR. E. H. BRADFORD stated that in that case death was probably not caused by carbolic poisoning, as in the fatal cases there has been a low temperature with vomiting and diarrhœa.

DR. BRADFORD showed a

CALCULUS FROM A CHILD TEN YEARS OLD,

which had evidently existed since babyhood. There was no history of blood or pain. He occasionally pulled on the penis, and at times held his water for twenty-four hours.

DR. FRANCIS MINOT reported a

CASE OF DEATH FROM HEART CLOT FOLLOWING
ETHERIZATION. THORACENTESIS.

DR. R. H. FITZ called attention to the importance of the alteration of the heart in explanation of the sudden death. In obese persons an increase of subpericardial fat tissue is to be expected, and is often so extreme as to interlard the muscular wall of the heart. Such individuals are frequently known to suffer from dyspnoea or asthmatic attacks, palpitation, and even angina pectoris. A feeble pulse and apex-beat with faint heart-sounds on auscultation suggest the existence of a "fatty heart." This condition, although possessing much of the clinical significance of a fatty degeneration of the muscular fibre of the heart, is to be distinguished from the latter. An atrophy of the muscle exists in the extreme cases, as in that reported by Dr. Minot, although anatomical evidence of incompetency, manifested by dilatation of the ventricle, was lacking.

The administration of ether, like any other depressing influence, for instance paracentesis without an anæsthetic, presumably enfeebled the action of a heart abnormally weak from the general cancerous disease as well as from the atrophy of its wall, and thus acted as an exciting cause in the formation of the thrombus. The growth of the latter progressed with great rapidity during the interval between the operation and the time of death. Flowing blood was necessary for its formation, and its origin was regarded as in the heart rather than in the pulmonary vessels from its adherence to the valve of the pulmonary artery, and the difference in color and consistency of the clot in the artery and the thrombus in the ventricle.

The limitation of the fatty infiltration of the heart to the wall of the right ventricle suggests the importance of an inquiry into the general symptoms of cardiac weakness, as well as the examination of the pulse and the auscultation of the heart, where doubt arises as to the propriety of administering an anæsthetic. In the present case the pulse indicated no enfeebled heart, nor was it likely, from the absence of evidence of alteration of the left ventricle, that the force of the apex-beat would have been lessened. Neither was there dilatation of the heart. Even the dyspnoea which may have been in part of cardiac origin was readily explained when evidence was found of accumulated fluid in the pleural cavity. The case not only suggests the importance of the comprehensive examination in doubtful cases, but also makes clear the difficulty, perhaps impossibility, of arriving at an absolutely correct diagnosis as to the actual condition of the wall of the heart.

DR. H. I. BOWDITCH remarked that he was confirmed in his previous judgment. Although he has allowed ether to be used in making a permanent opening, yet he has never done so for a simple aspiration. One lung being of no service, we should guard the use of the other.

Drawing blood at a first operation as a rule means cancer. In nine or ten cases in which he has got blood but one was benign. At a later operation it is a less important sign, being possibly a result of the first interference.

DR. C. B. PORTER could call to mind two cases of accident in the operation for a permanent opening. The cause was not recognized at the time. In one a

bronchus was wounded and the patient was drowned in his own pus, which invaded the opposite lung by this route, he lying on the sound side. In the other, respiration became embarrassed during etherization, a large trocar was thrust into the pleura, quickly finishing the operation, and the patient recovered.

DR. BOWDITCH said that if the patient *can* sit up he should do so, as if he lies at all it must be on the healthy side — increasing the risk.

DR. PORTER prefers to tap without ether when possible, and, except while going through the skin, believes there is little pain attending this course.

DR. MINOT stated that his patient of to-night's report always sat up until the last operation, when she lay on the diseased side and was tapped from below. There was no cough.

DR. F. I. KNIGHT said that in Dr. Minot's case the result might have happened without ether, and without operation. He himself, in a paper before this Society, had given abundant evidence that patients died in acute pleurisy from a variety of causes, which causes seem sometimes to be facilitated by the operation. He mentioned embolus of the pulmonary artery, syncope, both with and without operation, and one case of death from the rupture of a small vessel outside the chest. He repeated that Dr. Minot's patient might have died in the same way without operation. He would agree that care is needed in thoracentesis, but such a case would not keep him from the use of ether.

DR. LANGMAID, in answer to a question, said that, even making due allowance for the less care we take in etherizing dogs, it is a fact that they do die suddenly having been apparently in good condition the moment before.

DR. BOLLES said that death from ether is a rare thing. He reported the case of a child with inflammation of the middle ear and well-marked symptoms of meningitis. He etherized and cut into the mastoid process without finding pus. There was nothing unusual in the etherization, but as consciousness returned the mouth filled apparently with saliva, which flowed in streams, obstructing the respiration. He turned the patient on the face so that a cupful ran out, the chest being filled with mucous râles. The child died in a half hour. A free secretion of saliva or mucus is at times observed in etherization.

DR. WHITTIER said: I had hoped to strengthen the position which I shall take by the opinion of Dr. Bowditch. But I am unable to quote him in answer to this question: At what period in the heart's action is there the largest opportunity for the formation of a heart clot and the consequent pulmonary emboli? Is it during systole or during diastole?

I claim that neither the radial pulse nor stethoscopic examination of cardiac area declare with sufficient distinctness the abnormal condition wherein the diastole is so prolonged as to be a period more of danger than of rest, and that the pulse tracing is the only reliable indication and guide.

It is accepted on a standard that the time occupied in the complete cardiac movement is divisible into thirds, of which the normal systole takes one third and diastole the remaining two thirds. If these units of division be represented by spaced intervals, it will be clearly shown, that in proportion as the elements of the tracing normally found in the diastolic interval invade the interval belonging to systole, exactly and according to the degree of invasion is the evidence

and the measure of the prolongation of diastole and the larger opportunity afforded for cardiac thrombosis and consequent pulmonary emboli. The pulse tracing alone is a sufficient guide.

Dr. BOWDITCH reported a case of

ARRESTED PHTHISIS.

The patient lived to fifty-one, and had chronic pleurisy for two thirds of his life. Every few years crackling appeared under the clavicles. Although a microscope maker, he got as much walking as possible. There was no tubercle, but a general amyloid degeneration. The speaker would never give up a man who had the pluck to keep out of doors. Crepitation may last for twenty years.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

An adjourned annual meeting, followed by a stated meeting of the Society, was held November 26th. The first business was the report of the Committee on Hygiene. Dr. S. OAKLEY VANDERPOEL, chairman, which was read by the SECRETARY, and which consisted of four parts. The first of these, on

MORTALITY TABLES AND EPIDEMIC INFLUENCES,

was prepared by Dr. E. G. JANEWAY. From this it appeared that the mortality for the nine months of the year ending September 30th has been less than for the corresponding periods of the years 1881 and 1882, but somewhat greater, both absolutely and comparatively as regards increased population, than that of the same period in the years 1878, 1879, and 1880. There were 3604 deaths in 1882, and 2951 in 1881 in excess of 1883 for the three quarters comprised in the report, the cause for this difference being mainly attributable to the greater prevalence and fatality of the contagious diseases in those years. Then followed a table showing the differences in the zymotic diseases during the three years 1881, 1882, and 1883.

A comparison of the mortality from the various diseases during the first nine months of the past twelve years was then made. The deaths from small-pox were as follows:—

1872.....	853	1878.....	2
1873.....	107	1879.....	24
1874.....	222	1880.....	6
1875.....	1098	1881.....	364
1876.....	308	1882.....	258
1877.....	14	1883.....	12

In this connection a table was subjoined to show a comparison between the former and the present prevalence of small-pox, beginning with 1848. The work of systematic vaccination was commenced in 1875, and had continued up to the present time. Since that time the corps of the Board of Health charged with this work had performed 119,856 primary and 430,783 revaccinations, a total of 550,639. The work was initiated when a severe epidemic of small-pox was in progress, and on the two occasions where it had since developed, the Board of Health had been able to hold the disease successfully in check. There had been 780 deaths from it since the end of the epidemic in 1877, a period of six years, a number of them occurring among recently arrived emigrants. Without taking into account the fact that the city had trebled its population

in the time comprised in the table, the mortality from small-pox was only from one half to one fourth of what it was in any preceding six years, except between 1866 and 1871. Had the same mortality prevailed as in the years following 1848, instead of 780 deaths in these six years terminating with 1883 there would have been 7500 deaths. In other words 6500 people had been prevented from dying of small-pox. It was the duty of physicians to urge on the work of vaccination, particularly at present, since when small-pox had only prevailed to the limited extent of the six years just ending people became careless, and persuasive vaccination by public authority was more difficult to carry out. It was far more essential to keep up thorough vaccination now than to wait for the initiation of another outbreak of the disease, which would find its victims in the careless and obstinate.

The mortality during the first nine months of the past twelve years was then given from measles, scarlet fever, diphtheria, croup, whooping cough, typhoid fever, typhus fever, cerebro-spinal meningitis, malarial fevers, pneumonia, bronchitis, phthisis, and diarrhoeal diseases. "The tables show at a glance," continued the report, "the fluctuating character of the mortality from measles, scarlet fever, and diphtheria; from which it seems probable that, owing to the moderate number of deaths from scarlet fever this year, we should witness next year a marked increase in this disease; whereas for measles the probability would be that there would be a considerable diminution." Diphtheria was stated to be on the decline, and from the previous course of the disease it was probable that this diminished mortality might continue for a year or more longer. Pneumonia had produced forty-one less deaths than last year, but 235 more than in 1881, and 634 more than in 1880. The mortality from bronchitis was less than in either 1881 or 1882. Phthisis, on the other hand, had caused thirty-five more deaths in 1882 than in 1881, and fifty-nine more in 1883 than in 1882.

In referring to the diminished mortality from diarrhoeal diseases, Dr. Janeway spoke as follows: "No one is more aware than the writer of the fallacies liable to occur in comparing vital statistics; yet he feels that, making all due allowance for possible error, a considerable number of lives have been saved as the result of the employment of the summer corps of the Board of Health and of the active charity of New York City. These measures are sufficiently familiar to need no more extended mention."

After noting the fact that typhoid fever had made no very marked change in the past three years, the report was concluded as follows: The outbreak of typhus fever which began in 1881 seems terminated, as only ten deaths have occurred from this cause (during the present year). He who looks at the number of deaths which took place from this disease when it gained an entrance in New York in past years will again see the value of an actively interfering agency to prevent the spread of disease. But for the efforts of the Board of Health the disease would have spread greatly and extended over a number of years. Instead of a mortality of 225 in the outbreak of 1881-1883 there might have been a proportional increase, according to population, over what occurred in 1848 and the following years, when more than 4500 persons died of the disease; the equivalent of what would be over 10,000 for the present time. Judging from the annals of the past, a battle in which 10,000 persons were slain

would ever be commemorated in history. A battle in which perhaps more than that number of lives were saved from destruction by pestilence is a matter not deemed of any special moment. The moral of this is, that the medical profession of New York should see that its Board of Health is properly maintained, aided, and encouraged in its work. At times in the past physicians have from neglect or for concealment failed to notify the Board of Health of the existence of contagious diseases, with the effect of producing an epidemic in some instances.

The second part of the report of the Committee on Hygiene was by DR. O. D. POMEROY, and was entitled *Some Points on the Hygiene of the Ear*. It pointed out various ways in which ear trouble was apt to be engendered. The third part was on

SEWER GASES,

and was written by DR. STEPHEN SMITH. He strongly condemned the method of ventilating sewers adopted by the department of public works in New York, by means of perforated man-hole covers, which served only to fill the dwellings and streets with noxious vapors most prejudicial to public health. The specific gravity of the sewer gas was slightly greater than that of the ordinary atmosphere, and so, on escaping, it was held in the breathing stratum. What was needed, he thought, was an aspirating apparatus, and he recommended the adoption of metallic tubes connected with the sewers and carried to such a distance above the house-tops as to insure the diffusion of the gases in the upper air, where they could do no harm. If this were done, a current of pure air would be created down through the man-holes into the sewers, driving out all the sewage emanations through the escape pipes, and if these were placed even at intervals of one hundred feet he had no doubt the vaults would be thoroughly ventilated; while if they were placed at shorter intervals, the ventilation would be simply perfect.

The fourth part of the report was by DR. VANDERPOEL, the chairman of the committee, and was on the subject of

DANGERS TO THE PUBLIC HEALTH FROM THE ERECTION OF HIGH APARTMENT HOUSES.

The sanitary objections to these enormously high buildings affected both the inmates of them and the occupants of adjoining property. Among those affecting the inmates were the impossibility of complete isolation in case of the outbreak of contagious disease, the cutting off of the first three floors from sunlight, and the danger of miasm being conducted to the upper floors by means of the air-shafts employed for ventilation. Among the dangers to the occupants of neighboring property were the rendering of the streets damp and unhealthy by excluding the sun from them and the establishment of new currents of air, which were liable to cause smoky chimneys and interfere with the sewer ventilation of houses of the ordinary height.

The resignations of Dr. Austin Flint, Jr., and several other adherents of the National Code having been read and accepted, the

ADDRESS OF THE RETIRING PRESIDENT,

DR. DAVID WEBSTER, was delivered. In it he spoke of the marked prosperity of the Society during the year, and of the excellent work which had been

done in the prosecution of illegal practitioners of medicine.

The adjourned annual meeting then adjourned, and a stated meeting of the Society immediately followed, with the new president, DR. S. OAKLEY VANDERPOEL, in the chair. When the minutes had been read and approved, the

ADDRESS OF THE PRESIDENT ELECT

was listened to by the Society. In the course of it Dr. Vanderpoel suggested that the rich stores of material in the hospitals of New York, which were practically denied to the great mass of the profession, might be made available under the auspices of this Society for the study of relative methods of treatment, the influence of diathesis, the affiliation of various complaints and other interesting topics, and he strongly recommended the collective investigation of disease, a method which had of late been pursued with excellent results in England under the aid and encouragement of the British Medical Association. The self study of disease, he also thought, would be of great service in increasing our knowledge of certain disorders like dyspepsia, for instance, which caused a frightful amount of misery but killed no one. On motion, the suggestions of the inaugural address were afterward referred to the Comitia Minora for such action in regard to them as might be deemed advisable. At the conclusion of the address Dr. Vanderpoel announced the members of the committees on Hygiene, Ethics, and Prize Essays for the ensuing year, and appointed Dr. W. Gill Wylie to read a memoir of the late Dr. J. Marion Sims at the January meeting.

The report of the Comitia Minora, which recommended the election of fifteen new members, was then read, and the recommendation adopted, after which the paper of the evening, on

CEREBRAL EXHAUSTION,

was read by DR. J. LEONARD CORNING. While he believed the affection was a functional one, he was convinced that certain changes, of which the present state of our knowledge did not permit us to take note, occurred in the protoplasm of the brain-cells. Among the earliest symptoms to appear were great restlessness during the day and sleeplessness at night. There were apt to be severe pains in the vertex or superciliary region, and sometimes the pain was confined to the occiput, when the galvanic current was usually of great service. The head pains were followed by other symptoms, such as disorders of the memory and impairment of will power. Morbid irritability ensued, and frequent outbursts of uncontrollable anger were often noted. Disorders of the vaso-motor system were very frequent, and cerebral hyperæmia was apt to alternate with cerebral anæmia. Unevenness in the dilatation of the pupils was sometimes seen; and in some cases there was twitching of the abductor pollicis and other muscles. Other symptoms were morbid dread of society and morbid fear of all kinds, and hallucinations might sometimes occur. Among the predisposing causes were mentioned the nervous temperament and close application in some special and limited direction, and among the exciting causes, sexual excesses, disorders of menstruation, and mental worry of various kinds.

The essential pathological condition was believed to be an insufficiency in the nutrition of the brain-cells, and in the treatment the most important factor was

rest, which served to check the nervous drain going on and to replenish the exhausted vitality. A gradually increased amount of sleep was, therefore, to be secured, and in order to attain this end it was usually necessary to give the bromides temporarily. They were to be used in full doses during the day-time, so as to induce sleep at night. It was advised that the patient should be kept in a darkened room for from ten to fifteen hours out of the twenty-four, and that whenever he awoke he should be given a moderate amount of nourishing food in liquid form. Stimulus in the form of brandy or claret was allowed, and tonics, such as coca, iron, and phosphorus, prescribed. Phosphorus was believed to be of special service. Whatever tonics were given, however, systematic feeding was of the utmost importance. During his waking hours the patient was to seek recreation, all mental labor being strictly forbidden. In order to secure a good result great perseverance and the most careful regulation of the habits of the patient were required.

DR. PUTZEL said that his experience did not permit him to agree with the writer of the paper on several points. As to the circulatory disturbances alleged to exist in cerebral exhaustion the fact was often advanced, but no proof was ever offered. In the dead-house these disturbances were not seen unless there was some local disease present. One of the best proofs of his assertion was found in the fact that both cerebral hyperæmia and anæmia were sometimes said by equally good authorities to exist in the same patient. Thus, in one case which had come under his care ten or twelve physicians in New York had said there was cerebral hyperæmia, and a German specialist had said there was cerebral anæmia, while still another, of equally high standing, had pronounced that neither condition was present. Furthermore, ophthalmologists had become convinced that hyperæmia or anæmia of the retina afforded no evidence of the same condition existing in the brain. As to the treatment, he believed that the bromides did more harm than good. At first their use was often followed by an amelioration of the symptoms, but afterwards the good effect was lost, and they became positively injurious.

Cerebral exhaustion seemed to him to be due to three causes: The first was heredity, and while some patients inheriting a tendency to brain trouble were affected with organic disease, others suffered simply from cerebral exhaustion. The second was worry, and he doubted whether he had ever seen a case produced by over-work alone, without the element of worry. The third cause was general anæmia, and in cases due to this the ordinary ferruginous tonics would generally suffice for a cure. In the hereditary cases he thought it practically impossible to effect a permanent cure, as the trouble was liable to come back at almost any time. His general plan of treatment was a tonic and stimulant one, and he did not believe that absolute rest was beneficial. The tonic which he preferred was arsenic, and he considered this much better than phosphorus, which in his hands had never yielded any good results.

Both Drs. WEBSTER and ROOSA stated that the appearances revealed by the ophthalmoscope in cerebral exhaustion were as yet of no practical value, and DR. JACOBI remarked that this affection was not very clearly understood, simply because the brain was not as yet well understood. This organ could not be studied as a specialty, since it was dependent on every other or-

gan, and the observations of the general practitioner were needed to throw light on such a subject. In cerebral exhaustion the brain was used up by over-work, worry, etc., and as the circulation of the brain was in direct connection with the heart and muscles, it was necessary to take into consideration the whole system in studying the affection. If the brain was exhausted the whole system was apt to be affected. So far as we knew at present, it was a functional disease, although some affections which were formerly supposed to be of this character were now known to be organic in character. This was the case with infantile paralysis, which had been found to be in reality a myelitis affecting the anterior horns. As to the relations of the brain and heart, while at first the brain exhausted the heart, afterwards the heart acted in the same manner upon the brain. It was advisable in almost all cases of cerebral exhaustion, therefore, to keep the heart in as good condition as possible, and for this purpose there was no agent so useful as digitalis. Althaus, of London, had claimed wonderful things for the galvanic current in this affection, and he also had found it of service. He agreed, too, with Dr. Putzel, in regard to the efficacy of arsenic, which he was in the habit of administering for a considerable length of time in quite small doses.

Drs. A. H. SMITH, HARWOOD, and GARRISH also spoke, and the discussion was closed by DR. CORNING, who thought that heart trouble, when a complication, was dependent on the condition of the brain, since when the latter was remedied the heart got well of itself.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

C. B. NANCREDÉ, M. D., RECORDER.

THURSDAY evening, November 22, 1883. The President, DR. TYSON, in the chair.

LARGE INTESTINES FROM TWO CASES OF CHRONIC DYSENTERY, ONE OF THEM SHOWING PSEUDO-POLYPI.

By J. H. MUSSER, M. D.

CASE I. The patient had chronic dysentery; further clinical information cannot be given. No record of autopsy preserved. The specimen is from the museum of the Presbyterian Hospital, and I present it to-night on account of its rarity. It is a part of the large intestine, fourteen inches long. To the naked eye it shows thickening of the mucous and submucous layers, and hypertrophy of the muscular layer. On the surface of the mucous coat innumerable polypoid growths are observed, some pedunculated, some sessile. The sessile growths are from the size of a millet seed to that of a chestnut, round or ovoid. The others also vary in size from a pea to a large bean; their pedicle is generally from one sixteenth to one eighth of an inch long. The reporter remembers seeing the specimen when recently removed, and knows there were more pseudo-polypi than are here visible, many having fallen off from handling, etc.; that there was scarcely any healthy mucous membrane; that in this part of the intestine there was almost complete ulceration of the mucous coat. At one point a large stellate cicatrix, depressed in the centre, is noticeable, while all over the surface cicatricial lines are observed, most distinct about the bases of the growths.

Remarks. In connection with this specimen I would

like to call the attention of the members to a minute description of a similar specimen by Dr. Woodward. His article may be found in the *American Journal of Medical Sciences* for January, 1881, and is entitled *Pseudo-Polypi of the Colon; an Anomalous Result of Follicular Ulceration*. According to the writer the origin and development of these polypi is as follows: (1.) A granulating ulcerated surface of the intestine. (2.) Numerous islets of mucous membrane on this surface. (3.) "The formation of cicatricial contractions commenced in the infiltrated submucosa constricting the margins of the islets of mucous membrane which were further transformed by hyperplastic inflammatory processes until ultimately they acquired the form of pedunculated excrescences, and projected into the lumen of the intestine like so many little polypi," being pushed out by the contraction of the connective tissue. Although the surface of the mucous membrane appeared to the naked eye healthy, with the microscope it showed it was submucous connective tissue infiltrated with lymphoid elements. A pseudo-polypus was composed of a central portion of connective tissue and a peripheral portion of diseased mucous membrane, the former continuous with the submucous layer, the latter limited to the surface of the growth. The histological changes in the mucous and submucous layers resembled those of chronic inflammation. The remainder of the bowel showed follicular ulceration.

CASE II. A second specimen was shown where the clinical history had been of chronic dysentery with acute exacerbation. Here the mesenteric and lumbar lymphatic glands were not enlarged. The cæcum was surrounded by old lymph, the appendix bound down by adhesions and thickened. The cæcum was dilated; the transverse and descending colon contracted; the walls of the entire colon were thickened. On opening the large intestine it was found to be extensively ulcerated. The mucous membrane and the ulcers were strikingly anæmic and of a pale cream color; there were no points of hæmorrhage. The walls were thickened; the mucous membrane swollen; the ulcers were more numerous and larger in size at the cæcum. The smaller ulcers were the size of a dime; some of the larger extended around the gut, and were one half inch to an inch wide. The edges of the ulcers were regular, beveled, and thickened; the floor rather clean; the deepest did not extend beyond the muscular coat, the more superficial only includes the mucous membrane. The larger ulcers were on the tops of the folds of the intestines. A tenacious thick mucus covered alike the ulcers and the adjacent structures.

Condition of Other Organs. Liver enlarged and fatty. Kidneys markedly cirrhotic. Spleen normal. Heart slightly hypertrophied.

Microscopical examination revealed the changes in the intestine of chronic inflammation, and that the ulceration was of a simple nature and not due to tubercle.

A CASE OF CARCINOMATOUS SARCOMA OF THE LEFT TESTICLE.

Presented by DR. W. G. MACCONNELL.

This specimen was removed from a young man by Professor Brinton, at the surgical clinic of the Jefferson Medical College Hospital, on Wednesday, November 7, 1883.

History. Jacob A., aged twenty-six years, a clerk. About eighteen months ago he struck his testicle, in

mounting his horse, on the pommel of the saddle, from the pain of which he fainted. No inflammatory enlargement, however, of the organ ensued. Last May he noticed that the left testicle had begun to enlarge, which continuously increased in size until it had attained its present volume. There was a sense of heaviness in the tumor, but no pain was experienced until about two weeks prior to its removal, when he noticed a periodical pain of a burning nature, which, with the increasing size of the organ, caused him to apply for relief. It weighs about eight ounces, and measures in its long diameter four and a half inches, transversely three and a quarter inches, and about two and a quarter inches in thickness. No lymphatic involvement was present, nor was the cord involved; the veins of the scrotum were enlarged and prominent. The tunica vaginalis testis is slightly thickened and very opaque; the tunica albuginea is also thickened; a slight remnant of the epididymis exists in the form of a small fibrous lump. Its shape is somewhat that of a kidney, and upon section showed a moderately firm buff-colored tissue; it did not cry under the knife. In color and consistence it resembled the soft fibromata; distinct remains of the fibrous septa are to be seen; there are no cystic changes or any chondroid tissue present. Its macroscopical appearance and consistence suggested a spindle-celled sarcoma, and as such upon section I diagnosed it. Microscopically at a first examination, from the great ecstacy of the epithelium present, I was inclined to regard it as a pure medullary carcinoma, but after a careful study of several sections, I am inclined, by reason of the juvenescence of the connective tissue, both round and spindle cells being present, to call it a carcinomatous sarcoma. There was no history of syphilis, scrofula, or tubercle, nor had any member of his family ever labored under any form of tumor.

DR. NANCREDE called attention to the fact that modern microscopic study has shown that carcinoma of the testicle is a rare disease, most malignant tumors of that organ being really sarcomata. In this connection it is of much practical interest to note that the system becomes infected at a relatively late period of the disease, so that where a sarcomatous testicle is removed at an early stage of the disease prolonged immunity if not actual cure resulted. The inguinal and retro-peritoneal glands were those usually affected, their enlargement, by pressure, pain, etc., being the ultimate cause of death. Even more distant lymphatic glands are in rare cases involved.

DR. FORMAD agreed with Dr. Nancrede. Some years ago he had paid special attention to the study of malignant growths of the testicle and ovary. Of the former he had examined thirty cases, all of which were sarcomata. He did not believe in the existence of such a growth as true carcinoma of either the testicle, ovary, or kidney. The so-called carcinoma of those organs exhibits cells of a *connective-tissue* type rather than of an epithelial. Dr. Formad considered with many other observers that the so-called epithelial cells of kidney, testicle, and ovary are really *endothelial*, and gave reasons in support of this view. He further said that there is a variety of endothelial carcinoma occurring in the breast which is that usually described as alveolar sarcoma. Here the endothelial cells of the lymph spaces proliferate, but the glandular elements of the mamma do not participate. It is doubtless from the examination of such tumors that

Virchow, and Cornil, and Ranvier have gained the erroneous idea that true carcinoma takes its origin from connective tissue. The speaker would suggest the term "*endothelial carcinoma*" for such tumors instead of "*alveolar sarcoma*."

DR. DAVIS could not think that Dr. Formad was correct in absolutely denying the existence of carcinoma of the testicle, ovary, and kidney.

DR. MACCONNELL agreed with Dr. Nancrede as to the relative frequency of sarcoma of the testis, having examined a large number of such specimens. He could support the views of Dr. Formad as to the growths of the testicle originating largely in proliferation of the endothelia of the lymph spaces and tracts.

SARCOMA OF THE BREAST.

Presented by DR. G. E. DE SCHWEINITZ.

The speaker quoted the remark of Rindfleisch, that "the expression cysto-sarcoma is by no means to be conceived as the designation of a definite, perhaps round-celled, sarcoma with cysts, but it only tells us that a new formation with the textural character of histioid tumors has attacked the mamma and dilated its preformed cavities." This growth was removed from the person of a lady of middle age, married, but childless. She assigns no cause for its appearance. The growth of the tumor has been slow, it having originally been noticed six years prior to the date of operation. The weight of the mass immediately after removal was three pounds and one ounce. On palpation there was a distinct sense of fluctuation. The skin over the tumor was discolored, but not adherent. On section the growth is seen to be composed of two parts, the one about the size of a closed fist, and the other somewhat smaller. The section evacuated a quantity of bloody, mucus-like fluid. The centre of each mass is seen to be cystic, or, rather, the masses are the papillary and irregular excrescences which have protruded into the dilated ducts. The growth is composed of numbers of variously-shaped nodules, whitish or yellowish-white in color, but in some spots semi-translucent, and resembling somewhat colloid material. The microscopic examination of various portions shows similar results differing only in degree: Large, round-celled sarcoma tissue and some spindle cells, generally diffuse, but in places tending to alveolar arrangement. Here and there round, stellate, and spindle cells branched and anastomosing (mucoid tissue). Numerous blood-vessels, usually wall-less or mere channels passing through the tissue. In many places the sections show the enlarged ducts, cut transversely, and lined with a single layer of columnar epithelium. Surrounding them is a dense matrix of connective tissue. It may not be uninteresting to state that the specimen has been preserved in a solution of hydrate of chloral (twenty grains to one fluid ounce) after the manner originally recommended by Dr. W. W. Keen, with what success the beautifully fresh and natural appearance of the growth plainly attests.

—Dr. Henry Thompson, of Syracuse, has been found guilty of grave-robbing. The body stolen was that of a prominent resident of Camillus, a village near Syracuse, who died in March last, and it was discovered at the medical college in the latter place.

Medical and Surgical Journal.

THURSDAY, DECEMBER 13, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

THE PROSECUTION OF MANUFACTURERS OF ADULTERATED DRUGS.

WE stated in a recent editorial (November 22d) that several prosecutions were pending against vendors of adulterated drugs and milk in Massachusetts under the legislative act of 1882. A number of these cases have since been before the courts, and the convictions obtained against the dealers in adulterated milk are said to have already had an appreciable effect in improving the quality of the article sold in this market.

In the matter of drugs the policy of the Board of Health, Lunacy, and Charity is to prosecute the manufacturers who should and must know what they put upon the market, rather than the retailers, who may violate the law unwittingly. Accordingly charges of selling adulterated drugs were made against two firms of wholesale druggists of Boston, namely, Messrs. Rust Brothers and Bird, and Messrs. Billings, Clapp & Co. Tincture of opium was the drug selected upon which to bring the charge as being one of those in most frequent and general use. Under the Act of 1882 a drug is declared adulterated (1) if, when sold under or by a name recognized in the United States Pharmacopœia, it differs from the standard of strength, quality, or purity laid down therein; (2) if, when sold under or by a name not recognized in the United States Pharmacopœia, but which is found in some other pharmacopœia or other standard work on *materia medica*, it differs materially from the standard of strength, quality, or purity laid down in such work; (3) if its strength or purity falls below the professed standard under which it is sold. The State analyst of drugs found that the sample of laudanum procured from Messrs. Rust Brothers and Bird contained only .81 per cent. of morphia in the opium used instead of 1.20 per cent. according to the standard fixed by the Pharmacopœia of 1880. The sample of laudanum from the other firm, Messrs. Billings, Clapp & Co., was even more deficient in morphia, containing only .72 per cent., less than two thirds of the required amount.

The defense in each case raised the point that the public issue of the Pharmacopœia of 1880 was not made until several months after the law of 1882 went into effect. The book was issued October 26, 1882; the law went into effect the preceding August. The defendants claimed the right to take any pharmacopœia issued by the Society, even if they went back to

the first one of 1820, because the act of the Legislature does not specify any particular pharmacopœia.

The counsel for the Board held that either the Pharmacopœia of 1870 or that of 1880 must be in force, and according to the testimony of the analyst, Dr. Davenport, the tincture fell below the standard fixed by either book. But the standard of 1880 had been adopted before the law was passed. The fact that the printer did not finish his work in a year or more had nothing to do with the question. The law never meant to have any one of the six standards made from 1820 to 1880 open for choice.

The judge decided that it was unreasonable to claim that the Pharmacopœia of 1850 or 1860 was the present standard. The Pharmacopœia of the United States is the last one published. The statutes, however, went into effect before the Pharmacopœia of 1880 was published. The judge would, however, rule that either the book of 1870 or that of 1880 was the Pharmacopœia of the United States, and it was not necessary to decide which one of those two. Subsequently it was ruled that the Pharmacopœia of 1880 fixed the standard under which the government could proceed.

Practically the only change made in the strength of the tincture of opium as it should be made under the Pharmacopœia of 1880, and as it really was made by all fair apothecaries under the revision of 1870, is that now ten per cent. of the powdered opium should be put into the tincture, while formerly but nine per cent. was required. The same powdered opium is used as formerly.

The Board proved its case against both the firms, but the first one escaped the penalty, it not appearing in the evidence, although subsequently established in fact, that the person who sold the drug was an authorized agent. Conviction was also reached in a third case, the defendants in which were the firm of Noyes & Co., druggists of this city. The penalty in these cases is a fine not exceeding fifty dollars for a first offense, and a fine not exceeding one hundred dollars for each subsequent offense.

It is entirely unnecessary to dilate upon the injury done to the public and the profession by the manufacture and sale of adulterated drugs, especially of such a drug as laudanum. The law of this State to prevent such adulteration is a just and necessary one, and the Board of Health, Lunacy, and Charity should have the cordial support of the medical profession in its efforts to enforce it, especially when, as we are persuaded is the fact, it desires to avoid the infliction of undue hardship in the discharge of its duty. The activity of the Board will be directed, we understand, mainly against the wholesale manufacturer, for whom carelessness in the preparation of such an article as laudanum, or of citrate of iron and quinine, another drug for adulteration of which a charge is pending against Messrs. Billings, Clapp & Co., is a most lame and impotent plea. The retailer who acts in good faith, and can show the source of his adulterated supplies, we doubt not will be dealt with in a liberal spirit, and it is directly for his interest that the manufacturer should be imbued with a proper respect for the law.

The Boston Druggists' Association has, we are told, addressed a remonstrance to the Board on its present process, emphasizing the propriety of warning a delinquent firm before proceeding against it. Such a position is a singular one to be taken by such a body, and we do not see how the Board could possibly entertain it favorably. Honest and capable manufacturers should not depend upon the State analyst for information as to the quality of the goods they offer for sale; nor would they either expect or desire from the Board a negative permission to sell adulterated articles until positively, specifically, and individually notified that they must reform.

THE MARKINGS OF ELECTRICITY.

THE occasional markings on the bodies of persons who have been struck by lightning have been described, and in a very few instances drawn, by observers. The arborescent appearances at times shown have led to fanciful attempts to attribute to the lightning a power of photographing neighboring trees and other objects. Such a power has been soberly held by numbers of people, but we doubt if there are many individuals who would not rather regard the stories of these ecchymotic pictures with some sort of mild incredulity. The senior demonstrator of anatomy in the University of Glasgow, Mr. John Yule Mackay, has published in the *Glasgow Medical Journal* of November a photograph of these appearances as they were exhibited on the arm of a boy of thirteen. As these markings are exceedingly evanescent the securing them by photographic process was exceedingly fortunate, and suggests the idea that the popularization of photography by the instantaneous dry-plate process will prove a boon to the profession by the retention of transitory appearances, and that it will in this manner undoubtedly play a large rôle in the not distant future in medico-legal cases. The boy in question was struck by lightning about eleven o'clock in the morning with three other boys who were standing with him in the doorway of an empty stable. One was rendered unconscious, and the other three partially so. The boy who furnished the photograph was for some time after gaining consciousness unable to remove his hands from his pockets, where he had placed them before the accident; there was also a sensation of numbness and cold in the arms, and the boy fancied they had been broken at the elbows. Later, complaining of a burning heat, his coat was removed, and the markings discovered. These were of an arborescent character, stretching from below the left elbow to the shoulder, and throwing branches of a less complicated description across the left chest.

The marks were of a ramified, tree-like form, and seemed to radiate from two centres as if the lightning had first struck the arm in two places and had thence broken over the surrounding skin. They were believed by many to be photographic images of a yew tree or of the fronds of a fern, but unfortunately for the holders of this theory no vegetation of such description was within sight. For two hours these

markings retained their original appearance. They were of a red color; the skin was slightly raised over them, and the superficial heat of the arm was greater than that of the rest of the body. Four hours after the accident they were photographed, and though faded were still clear. At half-past seven they were hardly visible, and next morning had entirely disappeared. We are indebted to Mr. Gunn, chemist of Duns, the father of the child, for promptly securing the first photograph of a phenomenon which so many would otherwise regard as fabulous.

The boy's clothes were unharmed by the lightning, and the buttons and metallic substances in his pockets were uninjured.

Mr. Mackay discusses the reasons for the phenomena, and concludes that in accordance with known laws the current tends to divide in a branching manner if conduction be hindered or the current be weak. The marks do not correspond with the vessels of the region. Their red color does not appear to be due to a charring or burning of the skin, differing markedly from the surfaces sometimes seen, on which a stronger current has fallen. The author is led to believe that these appearances owe their existence to

a change in the blood of the capillary net-work lying immediately under the surface, and that this change is a coagulation of its albumen by heat, the coagulation following closely the distribution of the electric fire upon the surface.

MEDICAL NOTES.

— Editorials and medical notes, correspondence, and miscellany have had to yield to the pressure of papers and society reports in the present issue of the JOURNAL.

— Physicians' diaries and visiting lists for 1884 are beginning to make their appearance. Those published by William Wood & Co. and P. Blakiston, Son & Co. are both very convenient pocket-books with well-arranged pages.

— At the Congregation at Oxford on November 1st, Prof. Michael Foster, Fellow of Trinity College and professor of physiology, and Prof. Alexander Macalister, Fellow of St. John's College and professor of anatomy, were presented by the Public Orator for admission to the complete degree of M. A. *honoris causa*.

Deaths reported 2385 (no report from New Orleans): under five years of age, 689; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 459, consumption 346, lung diseases 293, diphtheria and croup 159, typhoid fever 70, diarrhoeal diseases 62, scarlet fever 54, malarial fevers 25, whooping-cough 20, measles 19, cerebro-spinal meningitis 11, puerperal fever eight, erysipelas seven, small-pox two, typhus fever two. From *scarlet fever*, New York 10, Philadelphia nine, Brooklyn seven, Chicago and Milwaukee five each, Boston, St. Louis, Baltimore, and Buffalo, three each, Pittsburg and Worcester two each, New Haven and Cambridge one each. From *whooping-cough*, New York, Philadelphia, Brooklyn, and Baltimore, three each, District of Columbia five, Chicago, Cincinnati, and Somerville one each. From *malarial fevers*, New York 10, Baltimore six, St. Louis two, Brooklyn, Pittsburg, New Haven, Charleston, Nashville, and Lynn one each. From *measles*, District of Columbia 10, New York six, Brooklyn, Chicago, and Baltimore one each. From *cerebro-spinal meningitis*, Chicago three, New York, St. Louis, and Cincinnati two each, Lowell and Taunton one each. From *puerperal fever*, New York, Brooklyn, Chicago, Boston, St. Louis, and Charleston one each, Nashville two. From *erysipelas*, Philadelphia and Baltimore two each, New York, Buffalo, and Providence one each. From *small-pox*, Philadelphia two. From *typhus fever*, New York and Charleston one each.

Eight cases of small-pox were reported in St. Louis; scarlet fever 31, diphtheria 25, and typhoid fever 13 in Boston; scarlet fever 16, and diphtheria two in Milwaukee.

In the 52 cities and towns of Massachusetts, with an estimated population of 1,161,283 (estimated population of the State 1,922,530), the total death-rate for the week was 16.56 against 18.59 and 12.81 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending November 17th, the death-rate was 23.2. Deaths reported 3828: acute diseases of the respiratory organs (London) 445, scarlet fever 138, measles 103, fever 81, whooping-cough 65, diarrhoea 60, diphtheria 34, small-pox (Sunderland five, Birmingham three, Wolverhampton one) nine. The death-rates ranged from 15.7 in Leicester to 33.4 in Manchester; Bradford 19.9; Birmingham 20; London 22.2; Sheffield 22.8; Newcastle-on-Tyne 23.7; Nottingham 24.3; Birkenhead 25.9; Leeds 26.3; Liverpool 26.4. In Edinburgh 19.9; Glasgow 29.5; Dublin 25.2.

For the week ending November 10th, in 172 German cities and towns, with an estimated population of 8,755,812, the death-rate was 22.1. Deaths reported 3723; under five years of age, 1140; consumption 480, lung diseases 389, diphtheria and croup 286, diarrhoeal diseases 141, scarlet fever 102, whooping-cough 62, typhoid fever 48, measles and röteln 48, puerperal fever 25, typhus fever (Halle two, Beuthen one) three. The death-rates ranged from 10.8 in Wiesbaden to 36 in Königsberg; Breslau 24.5; Munich 26.9; Dresden 28.1; Berlin 24.9; Leipzig 22.1; Hamburg 24; Cologne 17.5; Frankfurt a. m. 16.3; Strasburg 16.7.

The meteorological record for the week ending December 1st, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps:—

Data.	Barom-eter.	Thermome-ter.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM NOVEMBER 30, 1883, TO DECEMBER 7, 1883.

CARTER, W. F., captain and assistant surgeon. Relieved from duty at Washington Barracks, D. C.,—to take effect at the expiration of his present leave of absence, and assigned to duty at Little Rock Barracks, Arkansas. Paragraph 4, S. O. 224. Department of the East, November 30, 1883.

SHUFFELDT, R. W., captain and assistant surgeon. Now on sick leave, relieved from duty at Jackson Barracks, New Orleans, La. Paragraph 3, S. O. 224. Department of the East, November 30, 1883.

RICHARD, CHARLES, first lieutenant and assistant surgeon. Assigned to duty at Jackson Barracks, New Orleans, La. Paragraph 2, S. O. 224. Department of the East, November 30, 1883.

BOOKS AND PAMPHLETS RECEIVED.—American Neurological Association. Ninth Annual Meeting. Reported by Wesley M. Carpenter. Reprint. 1883.

A System of Human Anatomy, including its Medical and Surgical Relations. By Harrison Allen, M. D., Professor of Physiology in the University of Pennsylvania. Illustrated with 380 figures on 109 plates, many of which are beautifully colored: The drawings by Herman Faber from dissections by the

author. Section V., Nervous System. Philadelphia: Henry C. Lea's Son & Co. 1883.

Wiesen as a Health Resort in Early Phthisis, with Directions for Clothing, Diet, and Exercise in the Swiss Alps During Winter. By A. T. Tucker Wise, M. D., L. R. C. P., etc., etc. London: Baillière, Tindall & Cox. 1883.

On the Relation of Micro-Organisms to Disease. The Cartwright Lectures for 1883. By William T. Belfield, M. D. Reprinted from the Medical Record. Chicago: W. T. Keener. 1883.

Bacteria and the Germ Theory of Disease. Eight Lectures Delivered at the Chicago Medical College. By Prof. H. Grandle, M. D. Chicago: W. T. Keener. 1883.

On Photographing the Larynx. By Thomas R. French, M. D. Reprint.

Practical Pathology. A Manual for Students and Practitioners. By G. Sims Woodhead, M. D., F. R. C. P. E. With 186 colored plates. Edinburgh: Young J. Pentland. 1883.

Description of a Revolving Astigmatic Disk. By Charles A. Oliver, M. D. Philadelphia. Reprint. 1883.

The Possibility of Abnormal Ocular Conditions through the Sympathetic System Impairing the Function of the Uterus. By William S. Little, A. M., M. D. Philadelphia. Reprint. 1883. Catalogue of Dartmouth College and The Associated Institutions. For the year 1883-1884. Hanover, N. H.

A Catalogue of Medical and Surgical Books. By Robert Clarke & Co. Cincinnati. November, 1883.

SYPHILIS OF THE BRAIN AND MEMBRANES.

LECTURE.

A CLINICAL LECTURE DELIVERED AT THE PHILADELPHIA HOSPITAL, OCTOBER 3, 1883,

BY H. G. WOOD, M. D.

One of the Physicians to the Hospital, and Professor of Nervous Diseases in the University of Pennsylvania.

REPORTED BY WILLIAM H. MORRISON, M. D.

GENTLEMEN,—I propose devoting a few lectures to the consideration of cerebral syphilis. You have probably heard no didactic lectures on this subject, which is one of the most important in the whole range of nervous diseases. I believe that there are in these United States hundreds of people filling insane asylums and grave-yards prematurely because this affection is not recognized. As many of you have heard no regular lecture on cerebral syphilis I shall take the liberty of considering the subject somewhat didactically, using the cases for the purpose of illustrating and enforcing the important points to be remembered about this disease.

It so happens that I am able, in beginning the consideration of this affection, to show you a brain which was taken from a patient who died very suddenly a few days ago. The story of this case is that the man, F. B., aged sixty-two years, was a shoemaker, and had, during the last weeks, been in the out-wards of this institution, working at his trade. I wish you to note this point, that he was able to work with a lesion in his brain, which was undiscovered until suddenly the man died. A lesion was left to itself, necessarily lethal, but which might have been cured. On the 23d of August, we are informed, this man lay all day on a bench in a sort of stupid state. This is very interesting, for, as you will learn later, excessive somnolence is one of the most characteristic symptoms of cerebral syphilis. On the day following it was noticed that he frequently put his hand to his head as though in pain. There also seemed to be a partial loss of power in the lower extremities. The stupidity and pain in the head continued for three or four days, but did not attract enough attention to cause the man to be sent to the hospital, but suddenly he dies, and is received in the dead-house.

Here is a half of the brain. In the Sylvian fissure, at the position which I indicate, the membranes have grown fast to the brain. The brain and membranes are united together into a dense, whitish mass, which microscopical examination shows to be made up of small cells without any very regular shape, and among them are some large multi-polar cells. Beneath this mass is a large patch of brain inflammation and softening. I do not propose to go into the minute histology of cerebral syphilis, but only so far as is necessary to explain certain important clinical facts which bear upon the symptoms.

In the first place let me call your attention to the fact that in the great majority of cases cerebral syphilis originates, as it has here, as a disease of the brain membranes, and not of the brain substance; that even when a specific gummatous tumor destroys a portion of the brain substance the tumor originally started from the brain membranes; that the membranes are

primarily united with the tumor and form a portion of its substance, making the base from which it grows.

The next point in pathology which is illustrated to a certain extent by this specimen is that these tumors usually occupy the exterior of the brain. Sometimes a syphilitic tumor exists in the ventricles. I have seen cases where the tumor rose from the velum interpositum. The symptoms are then somewhat different from those which appear when the growth is on the outside. Very frequently the tumor develops in the fissure of Sylvius, where the membranes are abundant, and dip in between the lobes.

We find these tumors, or, as they are more properly called, exudations, in two particular forms. Sometimes they are irregular, globose, or lobate, as in the specimen before you. Sometimes instead of forming a distinct tumor they exist as a wide-spread exudation without any regular shape. A gummatous nutritive change at the vault of the cranium usually takes the form of an irregular, more or less illy-defined, tumor, while at the base of the brain the lymph is more spread out and tabular, so to speak.

I next approach the symptomatology of cerebral syphilis, but before taking up the symptoms I wish to refer to a single point. It is that the symptoms are due to a foreign body in the brain; in other words, there is nothing in the symptoms which is absolutely pathognomonic of cerebral syphilis. The more or less characteristic manifestations are not characteristic because the tumor is due to cerebral syphilis, but because cerebral syphilis especially haunts certain regions. For instance, if the symptoms denote an exudation at the base of the brain they simply indicate the seat of the lesion, but not its nature. We know, however, that exudations at the base of the brain occurring in adults who are not tubercular are, in ninety out of every hundred cases, due to cerebral syphilis, so that if there are symptoms of exudation in this situation we are almost certain that the brain disease is the result of cerebral syphilis. In the same way we know that syphilitic lesions are very common in the upper surface of the brain. If we have symptoms of a tumor high up we know that the probabilities, if the patient is past middle life, are in favor of brain syphilis. The symptoms are not pathognomonic, but they are often very characteristic because they indicate the existence of gross lesions in certain regions of the brain.

In regard to the etiology of syphilitic lesions of the brain, the fact that you obtain no history of syphilis is no reason for believing that the disease is not due to syphilis. Why it is we do not know, but certainly clinical facts show most positively that serious nerve syphilis is most apt to follow the lightest primary sores, and that where there are severe secondary symptoms serious cerebral disease rarely occurs. I of course leave out of consideration those cases in which the disease attacks the bones of the skull, producing secondarily disease of the brain. I repeat this. In the majority of cases where brain trouble of the character of which I am speaking develops there has been very slight primary trouble.

To illustrate this point I have brought here two cases which are probably suffering from cerebral syphilis, and yet in neither of them is there a distinct history of primary disease. In one of them there is apparently a very distinct history that primary trouble has not existed. I want you to have firmly fixed in your minds the fact that a negative history is of no

importance, while, of course, a positive history is of the greatest importance. If there is a history of distinct secondaries with the regular march of the disorder it will be an important aid in arriving at a correct diagnosis, but in very many cases you will find that the primary lesion has been slight and followed by slight secondaries, or that the patient denies altogether the existence of primary disease. Of course patients often deny this thing from willfulness, but many deny it not from willfulness but from ignorance. A case which I shall bring in acknowledges having had gonorrhoea, but positively denies that he ever had a chancre or chancroid. I see this thing continually in private practice. I have seen a number of cases in men occupying the highest positions of life, with healthy families, without any past history of specific trouble, with no history of a primary sore, and who have noticed no secondary symptoms, and yet undoubtedly the victims of cerebral syphilis, their whole lives depending upon the acumen of the physician in recognizing the true nature of their disease. Where, during any period of life, there has been exposure to the possibility of getting syphilis the mere fact that syphilis has not shown itself is not proof that the patient has not got it. It is in these cases that we see the finest and strongest brains melt down as if burnt out by a flame of fire, a fire which could have been extinguished if the physician had but recognized the nature of the trouble. I may seem to be too emphatic in regard to this matter, but I am so because the secret of success in treatment lies in the primary diagnosis.

In these cases the original disease usually dates far back. The primary lesion occurs it may be in youth, and the man reaches the age of forty, fifty, or sixty before the Nemesis of his misdeeds, in the form of a severe attack of cerebral syphilis, overtakes him. There are, however, cases in which nerve syphilis has developed almost immediately after the primary lesion. I have known one case in which within one month after the appearance of the chancre the patient was seized with numbness in the little finger and ring finger of one hand. The nature of the affection was not recognized, and the numbness persisted. Five or six weeks later the man had a violent epileptiform attack. There was a case of so-called precocious nerve syphilis. As a rule, ten, fifteen, twenty, or, as in one of my cases, thirty years intervene between the primary sore and the development of brain syphilis; but I have seen it several times within six months, and I have had a number of instances between three and eight months.

To sum up, we learn that the most important facts to remember are that cerebral syphilis is especially prone to follow light primary and secondary symptoms; that very frequently it occurs in persons who think that they have never had syphilis, — such persons may have had gonorrhoea with a concealed chancre, or they may have had a slight chancre which healed in a few hours, and was followed by very slight secondaries which have not attracted attention; and that usually it is a late phenomenon, although it may occasionally develop early.

We do not know what makes the syphilis attack the brain in these cases. There is a case reported in a French journal published in Bordeaux in which a man developed cerebral syphilis after an attack of sunstroke. Sunstroke, as you know, tends to produce inflammation of the membranes, and this inflammation once excited would be very apt to take on a syphilitic form.

Again, traumatism is sometimes followed by cerebral syphilis. There are a number of reported cases in which blows on the head have produced an outbreak of cerebral syphilis. I have had two cases in which syphilitic disease of the spine has followed an injury. Fournier and Buzzard believe that cerebral syphilis is especially prone to occur in those who use their brains to a great extent. It is possible that over-use of the brain may have some tendency to develop cerebral syphilis, but I think that it must be a very slight factor. Two thirds of the patients with nervous disease whom I see in this house have some form of nerve syphilis, yet very few of these people, if they have any brains, have ever used them. While occasionally there seems to be some exciting cause for the development of the lesion, yet in the great majority of cases we cannot say why it is that the disease has expended itself on the nervous system.

There are two distinct methods of development of symptoms. In some cases the disease declares itself suddenly, while in others the onset is gradual. The mass which I have shown you in this brain has not developed all at once. It has been growing for months, and probably for years, and yet in this case no one suspected anything wrong with the man, who was able to work with this large mass in his brain, until suddenly he was taken ill. A physician was called, and in a day or two he was dead. There you have, what is very frequently seen, a sudden outburst of symptoms. It is a very peculiar fact that a gummatous exudation, mass, or tumor, may go on developing for years without producing any symptoms, until suddenly the patient will be swept down by an outburst of symptoms.

In this woman whom I have brought before you, I do not know whether the disease is specific or not, but I do know that she has a basal growth of some kind; that she has been married to a drunken, worthless, husband; that she has lived a miserable, wretched life, and that her own habits as regards the use of alcohol have not been what they should have been. The chances are greatly in favor of her having been exposed to the cause of specific disease. The past history, and the knowledge that she has a growth at a part of the brain where these growths especially arise, renders it extremely probable that this is a case of specific disease. You see that I do not make a positive but only a probable diagnosis, and that is all that can be done in the majority of these cases. Let me here give you a practical point in regard to your own bearing. I have come to consider the history given by patients so worthless that I rarely inquire for it. If you are called to a man in a high position in life, a banker, a judge, or a preacher, you may be little better than a fool if you take the man back into the dead and rotten past and rake up memories which had better be forgotten. You have in your own hands the touchstone which will enable you to determine with sufficient certainty for all practical purposes whether or not the disease is syphilis. There are cases in which it is better not to ask, and if you habitually trust the statements of patients you will sometimes be misled.

I have brought this woman before you to illustrate the suddenness with which the explosion of the disease may occur. She asserts that she was perfectly well until one day, when she suddenly became blind. She has not had the symptoms of a clot, but those of a growth at the base of the brain.

This second case, the man suffering from headache

and progressive hemiplegia, illustrates one or two points to which I have referred. In the first place, in regard to the man believing that he has never had specific disease. He admits that he has had gonorrhœa, but denies all specific trouble. In the second place, it illustrates the point that the symptoms may come on gradually. The history of this man is that for eleven months past there has been a gradual loss of power in one arm, one leg, and one side of the face. I want you to remember what I have said in regard to the symptoms of cerebral syphilis being chiefly the symptoms of a gross lesion in some part of the brain. There may be monoplegia, hemiplegia, or paraplegia, according to the seat of the tumor. In this man there has been hemiplegia which has developed gradually. What does this slow development mean? It always means that there is some growing, progressive lesion. When there is a progressively developing hemiplegia there must be a progressive growth. The symptoms only indicate that this man has something growing in his brain. Whether the growth be syphilitic or not must be determined from other circumstances.

We have learned that the symptoms of cerebral syphilis are those of a gross brain lesion of some kind. If the tumor is over the centres which preside over word memory and word thought, or, in other words, if the tumor is down in the Sylvian fissure, pressing upon the island of Reil, there will be aphasia. If the tumor or growth is, as frequently it is, at the base of the brain, there will be paralysis of the parts coming from the base of the brain, and especially of the nerves which supply the eye. Basal growths not tuberculous, paralyzing the oculo-motor and other nerves supplying the eye, are rarely anything else but syphilitic. Syphilitic basal growths are very frequent. Remember, then, that centric squint, dilatation of the pupil, ptosis, and paralysis of the ocular muscles are in an adult almost certain evidence of cerebral syphilis.

Palsy of the facial nerve, however, has no such significance. You know the course of this nerve: at the base of the brain it is exposed like the other nerves to the effects of cerebral syphilis, but it so happens that the facial nerve passes through a long bony canal, and that it is very prone to rheumatic and other affections of its sheath, which cause swelling, pressure, and consequent paralysis. In nine out of ten cases peripheral palsy of the face is not due to syphilis. Trigeminal palsy, or palsy of the sensory nerve of the face, is sometimes, but not commonly, the result of syphilis. Occasionally *anæsthesia dolorosa* is produced by syphilis. This is a condition in which there is a loss of sensibility of one side of the face associated with the existence of exquisite pain. The affection results from a lesion of some kind within the skull pressing upon and at the same time inflaming the trigeminal nerve. There is loss of sensation because the nerve is pressed upon, and there is pain because the nerve is inflamed inside of the point of pressure. The sensation is referred to the peripheral distribution of the nerve.

The sudden attacks may involve, as they did in the woman I showed you, the special senses. They however usually affect the brain as a whole, and there are sudden epileptiform attacks, constant headache, meningitis, or a sudden attack of congestion of the brain, which may be of the nature of apoplexy, with or without hæmorrhage.

In this fourth patient we have the statement that

five years ago, when he was thirty-five, he had a sudden attack of epilepsy. When epilepsy comes on for the first time after the age of thirty it is almost always due to some gross lesion of the brain. I have never seen a case of epilepsy developing in an adult, in which some brain lesion, such as softening or a tumor, or something that the hand could be put on, could not be found.

Returning to our first patient, we find that in addition to the blindness, she is suffering from trigeminal palsy. Under treatment the palsy has diminished, but it is still quite marked. At first a pin could be introduced against the cornea without producing any reflex, and without her knowing it. There is, at the same time, paralysis of the facial nerve. She cannot entirely close the eye. When I saw the case for the first time the left eye was enormously swollen, and there was great chemosis in the cellular tissue in front of the eye. The eye-ball was protruded to such an extent that I at first thought that there was something growing in the orbit. When I returned from my vacation I found the eye-ball shrunken and the tumor all gone. The woman had simply paralytic ophthalmia due to the palsy of the trigeminal nerve. The protrusion was so great as to justify the diagnosis of a malignant tumor springing from the orbit, but was due simply to the intense congestion and inflammation of the cellular tissue surrounding the eye-ball, with affection of the eye.

Turning again to the patient who developed epilepsy in adult life, I desire, as I may not have the patient before you at the next lecture, to point out one very curious symptom, which is almost characteristic of cerebral syphilis. About four or five months ago the man became suddenly deaf, and it was only by yelling in his ear that he could be made to hear. This came on without any discoverable cause, and within a few hours, continued two or three days, and then he began to regain his hearing and, without any apparent reason for so doing, in forty-eight hours he could hear as well as before. On questioning him, I find that he has had another curious symptom. For two or three days he lost the power of speaking. This went away suddenly. He says that he could not think words. He has had, in other words, a temporary, paroxysmal aphasia, as well as a temporary paroxysmal deafness. There are cases of a sudden loss of power in one arm, coming on within a half an hour, and after lasting for a few days passing away. A few weeks later there may be numbness of the foot, developing into a hemiplegia lasting a few hours and followed by a gradual restoration of power. Then there may be an epileptiform attack with loss of power in one side, which is rapidly recovered from. It is rare that the organs of special sense are involved. In this man you have an instance of what I have never before met with, that is, paroxysmal deafness. The important fact to be remembered is that these inexplicable, sudden, varying, temporary nerve attacks, when not dependent on hysteria, are very characteristic of cerebral syphilis. They are dependent on the fact that cerebral syphilis is prone to develop with great rapidity after a period of latency, and to cause sudden and violent congestions in proximity to the tumor. In this man there was congestion of the higher brain, and a discharge of nerve force producing an epileptiform attack. At another time a sudden congestion and drowning out of the sense of hearing; and again, a sudden blush of congestion, affecting the

island of Reil, and word power was lost. In another case the cortical centres of motion in the arm are involved; or it may be the centres controlling motion in the leg, or it may be the powers of the brain which are connected with movements of the eye which are affected, producing a temporary monoplegia, or a squint, ptosis, or dilatation of the pupil, according as the case may be. These strange, unaccountable, temporary attacks of paralysis, now here, now there, are very characteristic of cerebral syphilis, provided hysteria is excluded. The difficulty comes in when hysteria and syphilis are associated.

There is one peculiar symptom of this disease which I have not yet mentioned because none of these cases illustrate it, that is, a strange somnolence. If you are called to a case, and find that the patient sleeps hour after hour, or day after day, and if on examining him there seems to be nothing the matter, the chances are greatly in favor of his having cerebral syphilis. You may also find a history of past headaches, or of epileptiform attacks, or if, on examining the eye ground, which you should always do in doubtful cases, you find choked disks, you know almost certainly that the disease is cerebral syphilis. Sometimes instead of somnolence there may be sleeplessness. Sometimes the sleeplessness precedes the somnolence. Sleeplessness occurs in almost all forms of brain disease. Somnolence is rare. It occurs in pachymeningitis, which is, in fact, very often due to syphilis, and in the gradual softening of the brain in old people. Excluding these diseases, this symptom is very characteristic of cerebral syphilis. I saw a case last week of headache, general loss of mental and physical power, and oculo-motor palsy, and the patient stated that before he had any severe symptoms he would go to sleep over his work. He would have to quit work and go home about four o'clock in the afternoon. He would then go to sleep about five and sleep until nine or ten the next morning. If he had been seen at this time, the proper diagnosis made, the touchstone applied, and the necessary treatment instituted, long years of disablement would have been avoided.

There is only one other point in reference to the symptoms of cerebral syphilis to which I shall call attention to-day, namely, that very frequently an acute attack of meningitis will be lighted up by cerebral syphilis. A man has, it may be, a chronic meningitis. He begins to have headache, which is nearly always present in cerebral syphilis. He goes to his work, is suddenly taken sick, has high fever, becomes maniacal, and is hurried off to an insane asylum, suffering it is said from acute mania, and dies,—dies of the epidemic of ignorance which prevails to such an extent among many physicians.

Probably you will remember this better if I relate a couple of cases. A young man came home one afternoon and sat down in his store, which was connected with the house. After sitting there a while, he suddenly commenced to scream. He was carried up-stairs, and he began to have convulsions. A believer in homœopathic dilutions was called, and ordered him the one thousandth part of nothing. The consequence was that every time the man was given the dose he went off into a convulsion, and the hard, rapid pulse and high temperature continued. A physician was then sent for, and at first glance thought that it was a case of hysteria, and proceeded to give an *assafoetida* injection. The moment the syringe touched the anus such a convul-

sion was excited that the doctor went one way and the patient another. The physician then recognized the true nature of the attack and diagnosed acute meningitis. He bled the man twenty ounces, and he became quiet. The patient was carefully watched, and when the convulsions recurred ten or twelve more ounces of blood were removed by cupping, and he again became quiet. The man was bled altogether at least thirty ounces. The result was that the next morning instead of being in an ice box the patient was awake and rational. When he became strong enough to attempt to get up, a slight hemiplegia was discovered. The hemiplegia was incomplete, and it was not probable that it was due to a clot, for a clot after such an attack would be large enough to produce complete hemiplegia. I saw the case a day or two later and diagnosed it as one of cerebral syphilis. Under proper treatment the man rapidly recovered, but before he did get well the sign of the beast came out, not on his forehead, but on the palm of his hand, in the form of a patch of psoriasis.

Some years ago I saw a case at the University Hospital, which I diagnosed as cerebral syphilis, gave the man iodide of potassium, and sent him home. That night the man became unconscious and furiously delirious. A doctor afflicted with ignorance was sent for and diagnosed strychnia poisoning, and treated him for strychnia poisoning for four days. The man got no better, and it was thought well to send for the doctors who were asserted to have given the strychnia. The man of course died, and the autopsy revealed the correctness of the diagnosis which I made as soon as I saw the patient, namely, acute meningitis supervening on the chronic disease.

TWO CASES OF PARAPHASIA. ONE WITH AUTOPSY.¹

BY DR. S. G. WEBBER, M. D.

THE following case is of interest clinically and pathologically on account of the peculiar form of disturbance of speech associated with lesion of the supra-marginal convolution, and on account of the pathological changes elsewhere.

Mr. — was attacked suddenly with an inability to make himself understood. He was seen by Dr. Bundy, who gave me the particulars of the attack. There was no paralysis of the limbs. The patient could articulate perfectly, could put words together, and made an effort to talk, but the words were not used in their right relations. Wrong words were substituted for those which he evidently wished to use. Writing and reading were not tested.

Two or three days after he entered the hospital under Dr. Denny, who kindly gives permission to use the record, he was unable to talk much, and gave no history of himself, except that he complained of a feeling of pressure on the left side of the head, and a slight pain in the same region. There were no local symptoms. He was rather excitable, and was said to have attempted suicide. A double-edged knife was found on his person.

He slowly improved, talked better when he was ex-

¹ Read before the Boston Medico-Psychological Society.

cited, was at times depressed, thought his mind was failing because he could not remember the first person plural of a Greek verb ($\beta\omicron\upsilon\lambda\epsilon\upsilon\omega$). Once he had hallucinations of vision, perceived by himself to be such. There was an inability to write a sentence correctly which was dictated to him. He substituted a wrong word for one which was given him. A few days later he wrote more accurately from dictation.

I saw him only a day before his leaving the hospital. He then said he felt dull in the morning, clearer in the afternoon. There was much tremor of face and hands. The right pupil reacted more sluggishly, did not dilate so widely as the left.

After he left the hospital I met him once. He was slightly peculiar in his manner, a very little excited, talked perfectly well, showed nothing unnatural in his gait, nor in the motions of his face or hands. There was only the peculiar excitability, which seemed to be rather an individual trait than anything pathological.

Three months after he was in the hospital he was brought in upon the surgical side, having cut his throat. Dr. Draper, who made the autopsy, kindly allowed me to examine the brain.

The pia mater over the vertex, and on each side as low as the fissure of Sylvius, and nearly to the anterior

extremities of the frontal lobes, was rather thickened and opaque. At the base it was firmer than usual, and bound together the vessels and nerves more firmly than normal. The arteries at the base were atheromatous in patches. This change was rather more marked in the middle cerebral and its branches, especially on the left side. The pia mater was not adherent, came off readily without tearing the cortex, excepting possibly in two very small spots on the upper surface of the temporal lobe, within the fissure of Sylvius. The posterior third of the first (superior) frontal convolution and the adjacent portion of the ascending frontal were slightly rougher after the pia was removed than the other convolutions. These parts were also slightly yellow in tinge, and contained many small dilated arterioles (miliary aneurisms). These aneurisms were scattered irregularly over the rest of the cortex, most numerous on the left side. Several cavities containing serum, without discolored walls, varying from one eighth to three eighths of an inch in diameter, were found in the white substance of the occipital lobes. Some of these had a vessel leading from them, around which the cerebral substance was firmer than usual, and the vessel seemed to be plugged.

In the left hemisphere, just above the roof of the lateral ventricle, was a yellow spot about half an inch in diameter. At the extreme posterior end of the fissure of Sylvius, just above its upper margin in the supra-marginal convolution, was a cavity about three fourths of an inch in diameter; this cavity extended into the white substance towards the lateral ventricle, and was filled with dark-red serum and crossed by many bands of fibrous tissue. In the outer member of the right lenticular nucleus adjoining the external capsule, but confined to the gray matter of the nucleus, was another old hæmorrhagic cavity, pear shaped, one fourth by one half inch. In the left frontal lobe the perivascular spaces were unusually large.

Around many of the dilated blood-vessels or aneurisms the spider cells were more prominent than elsewhere; the nerve cells seemed to have been pressed aside and crowded together. In one section the spider cells seemed most numerous, in another the nerve cells showed more plainly.

The outermost layer of cortex containing no distinct nerve cells was rather thick; the blood-vessels in the layer showed very distinctly, more so than usual. The deeper layers of the cortex did not differ materially from normal except about many of the blood-vessels.

Around many of the medium and small, not smallest, arteries of the cortex there was considerable change, the tissues were more deeply stained, and the spider cells were increased in number and in size, taking the carmine much more readily than usual, and not showing the same delicate structure as in other parts, often, also, filled with a homogeneous substance, staining evenly and having no nucleus. The walls of the blood-vessels were considerably thickened, resembling closely syphilitic arteritis.

The extensive disease of the arteries through at least a part of the cortex is interesting in view of the mental symptoms, not so marked as to lead one to call him insane, yet he showed an erratic and eccentric tendency.

The chief interest, however, is in the disturbance of speech and the cerebral hæmorrhage. The particulars of the attack are not complete, it is not known whether he was unconscious, or whether there was any tem-

porary paralysis; when he first came under observation there was neither of these symptoms.

The disturbance of speech was not that most frequently seen in aphasia, neither the amnesic nor the ataxic (anarthria), it was rather the confusion of words, "the inability to properly connect word images and the corresponding conceptions, so that, instead of the ones corresponding to the sense, misplaced or entirely incomprehensible word-images present themselves." Kussmaul calls this "paraphasia."

Kussmaul has described "word deafness" and "word blindness," which Wernicke names "sensory aphasia." The centres for these defects are located by Wernicke along the margin of the fissure of Sylvius in the first temporal convolution. Wernicke locates the lesion in paraphasia in the medullary tract connecting these centres of sensory aphasia, if I may use such an expression, with the speech centre in the isle of Reil. In the present case the lesion was just outside of this tract, yet so near that a hæmorrhage might indirectly, by exercising a moderate pressure, cause a temporary interruption in the function of the nerve fibres passing through this tract. That permanent damage was not done is shown by the fact that in a short time the power of normal speech was fully restored.

Fränkel¹ gives an interesting case in which there was loss of speech, of the power to write, or to understand speech or writing; the ability to understand writing and to talk returned, but the patient was still unable to understand speech. In our patient all forms of aphasic disturbance disappeared.

So far as this case is of value it tends to confirm Wernicke's views, yet it does not closely define the seat of the conducting tracts or of the different centres concerned in understanding or originating the different forms of symbolic communications.

In connection with this case I may report the following:—

Mr. B. was brought to me last June by Dr. Doe. In early part of May he found, on his way home in the cars, that he could not use the word he wished to, yet he knew what he wanted to say, and knew he used the wrong word. Also he could not write correctly. Three or four days after, he fainted in Dr. Doe's office. The use of the wrong word at that time was scarcely perceptible to one conversing with him. His general health was good; there was a slight systolic souffle at the base. June 1st he went away for a rest, staying ten days. On his return he was slightly better. Writing was not clear; he still confused the words. After his return there was a slight staggering or limping in walking, but so slight it was not possible for his friends to say which leg was at fault. He had, on the whole, become worse, and two nights before I saw him he had much trouble with his speech, and staggered much. A sensation of coldness behind the left ear, which had annoyed him for a year, still persisted; he had no headache; taste was natural; at times there was tinnitus in the left ear; no dizziness, no diplopia, no sensation of numbness. He said he could not read much, and on testing him it was found that he could not read more than a word or two correctly, would miscall the next word.

The pupils reacted naturally; the eyes moved naturally; the right side of the face was slightly drawn up; the tongue could not be protruded beyond the teeth. There was moderate incoordination of the hands, not

at all marked. The left patella reflex was less than on the right; sensation did not seem to be affected. In walking sometimes one leg seemed to be the weaker, sometimes the other; probably both were weak.

During the examination he could make himself understood only when he used short sentences. In attempting to use longer phrases wrong words were used which did not belong together. He seemed to understand all that was said, and when he was advised to stay at his cousin's house instead of taking a long trip to visit his sister he showed much emotion, and wept. Subsequently he failed mentally and physically still more, and in a few weeks died. There was no autopsy.

A CASE EXEMPLIFYING ONE OF THE LATER LESIONS OF SYPHILIS, WITH REMARKS.

BY ROBERT H. GRANDIN, M. D., NEW YORK.

THE case I would embody in this paper may well serve as a text for the few remarks I desire to make concerning a scourge, which, striking as are the advances of the medicine of to-day over that of yesterday, too often still thwarts the best directed efforts of the physician. It is in its later stages particularly that syphilis shows its destructive virulence, and when brought face to face with one of the tertiary lesions the question forces itself, Do we, as physicians, lay sufficient stress on the necessity of prolonged treatment, and do we bring to bear sufficient moral condemnation on the man or woman who, the subject of syphilis, communicates it to another?

My case is, in brief, as follows: Mrs. A., age thirty-five, married for fifteen years; one child fourteen years ago. This only fruit of the union was born syphilitic, and is now living syphilitic. Its mother had well-marked secondary symptoms towards the end of her gestation, and its father has not been as yet cured of the disease which he transmitted both to mother and child. My patient was variously treated by various gentlemen, at one time having been greatly salivated. My knowledge as to the nature of the treatment she had been subjected to up to a few months before coming under my care, is limited to the fact that, at one time, she received pills containing the green iodide of mercury. About August of the present year, whilst at Richfield Springs, without any special premonitory symptoms, she had a paralytic stroke, was a short time afterwards brought to this city, placed under my charge, and presented the following physical condition: There existed partial hemiplegia of the right side of the body; locomotion was just possible with assistance, use of right arm *nil*; tongue deviating a little to the right; pupils equal; vision diminished; temperature equal; control over bladder and rectum; loss of speech; no anæsthesia; slight contracture of the flexors of the right arm; frequent somnolence and nervous irritability; electrical reaction fair; laryngoscopic and ophthalmoscopic examination negative.

From the history of the case, together with the physical signs, the diagnosis of gummous tumor of the left side of the brain was the most probable one. My prognosis was very guarded as to ultimate complete recovery, with the chances in favor of recovery from the hemiplegia. I was shown the prescription she had been given by an able practitioner of Richfield, and I continued it for a time with slight modifications. In a

¹ Berlin. klin. Wochenschr., August 29, 1883, page 501.

word, the treatment for the following six weeks consisted in liberal diet, massage, the faradic current to the affected muscles, ferruginous tonics, and the iodide of potash increased cautiously from thirty grains daily up to ninety grains, the limit of gastric tolerance in her case. Under this treatment the improvement was gradual but very marked up to the first of October, at which time she could walk unassisted, could use her thumb and forefinger to a degree, the contracture had almost wholly disappeared, the tongue no longer deviated, and articulation, to the extent of a few words, was present, though there was evident forgetfulness of the sound of words and inability to properly coördinate the muscles of the larynx. At this stage she had a menorrhagia, became melancholic, began to refuse her food, and a crop of syphilides appeared on her body irregularly distributed. I ordered the mercurial ointment, beginning with two scruples by inunction daily. On the 16th of the month she began to have "spasms," as her friends called them. I never happened to see her in one, but from the description given me I judge them to have been epileptoid in character, varying from one to six daily. I ordered one half drachm of the bromide of potassa daily, in divided doses, with the effect of subduing them for a time. Her condition, however, generally, had simply retrograded. Locomotion was lost, contracture and deviation of the tongue had returned, and there was a slight drooping of the right angle of the mouth. Great mental depression and cephalalgia. Suddenly, on the morning of the 31st October, after a severe convulsion, she passed into a comatose state, in which I found her a few hours later. The breathing was stertorous; incontinence of urine and feces; pulse 100, and feeble; temperature subnormal by a degree; frequent clonic convulsions. My prognosis was exceedingly unfavorable, and I asked a prominent specialist of this city to see the case with me. After a careful examination he agreed with me as to the probability of a speedy fatal issue, though he thought as I did that the patient might last a week. As for ultimate recovery, we agreed there was no chance. He suggested the substitution of the iodide of sodium in place of the potash salt, and of the stronger mercurial ointment (Squibb's) instead of the ordinary. I availed myself of his suggestions, and thereafter she received two drachms of the iodide of sodium combined with a half drachm of the bromide of potash in divided doses by rectal suppository, and a drachm and a half of the ointment, daily, with nutrient enemata (brandy, milk, cream) at regular intervals. On the fourth day from the onset of coma, the rectum refused the suppositories, and they were ordered by the vagina. The enemata were still retained. On the fifth day the patient was momentarily partially conscious for a few hours; towards evening the menses appeared, and the suppositories had to be omitted altogether. At the same time, notwithstanding great care towards prevention, there was slight salivation, and the ointment was discontinued. Convulsion after convulsion, of slight duration, succeeded one another, the temperature, which had been a degree or two above the normal for some days, increased to 104° F. (pulse 130), and remained at or near this point up to within four hours of the fatal issue. The stertor increased, ptosis of the right eyelid supervened, contracture of the right flexors increased to an extreme degree, and, early the morning of the sixth day, the patient died.

Remarks. The necessarily long clinical history of

this case forbids my taking up much further space. My remarks, therefore, will be few and to the point. The chief interest in the case centres in the localization of the lesion or lesions. Without post-mortem evidence any deduction is, of course, hypothetical. It is probable, however, that the symptoms yield us more evidence towards a correct diagnosis of the site than is usual in cases of the kind. Heubner, in his admirable *Analysis of Cerebral Syphilis*,¹ makes the useful subdivision into three fundamental symptomatic types, based on anatomical grounds. In the first there are psychological disturbances with epilepsy, incomplete paralyses (seldom of the cranial nerves), and a final comatose condition, usually of short duration; in the second there occur apoplectic attacks, hemiplegia, somnolence, phenomena of unilateral irritation, and, generally, paralyses of the cerebral nerves; in the third the course of the disease is similar to that of dementia paralytica. My case must, evidently, come partially under the second subdivision. I say, partially, for, to my mind, and the same idea was broached by my consultant, we must look in this case for a more generalized lesion than local growth, namely, an affection of the arteries. From a state of fair general health my patient had a slight apoplectic attack, emerged from it hemiplegic, and thereafter, notwithstanding rational treatment, slowly retrograded, with periods of improvement, up to the coma which ushered in the fatal issue. There existed paralyses of some of the cerebral nerves as well as of some of the motor nerves. The lesion, hence, cannot have been localized, but rather disseminated within, of course, limits. Heubner's pathological investigations have shown, that the lesion giving rise to the symptoms of his second subdivision is usually, if a new growth, situated at the base of the brain, either in the dura or in the subarachnoid space. In other words the lesion lies deeper than the covering of the inner surface of the bone, or than the bone itself. "It is evident that while the paralyses of the cranial nerves, in this form of the disease, are produced by the exudation at the base of the brain, the hemiplegias are due to changes in the great ganglia."² These changes in the great ganglia are secondary to disease of the arterial tract supplying them. The ultimate effect of this syphilitic disease of the arteries is, still according to Heubner, to cause a narrowing of the lumen of the arteries, whence insufficient blood supply and consequent degeneration of the ganglia. Now the arrangement of the cerebral arterial system is such that "the gray cortical substance of the brain, and the white medullary substance connected with it, as far as the roof of the ventricles, is supplied with blood-vessels on an entirely different plan from that which exists in the white substance at the base, and in the ganglia which lie above it and form the floor of the ventricle."³ The result is, in brief, that the arteries of the white substance are terminal, and those in the gray are collateral. When, then, there occurs a narrowing of an arterial lumen, that portion of the brain is, evidently, most in danger where the arteries are terminal. This is the basal portion of the brain; and it follows from all this that the effect of a narrowing of the lumen of one or other of the arteries supplying the base of the brain is apt to be of a permanent character, from the very fact that there is no collateral supply.

¹ Vide Ziemssen, xii., Am. ed.

² Vide Ziemssen, xii., p. 330.

³ Heubner, loc. cit., page 331.

I have borrowed at such length from Heubner because his remarks seem peculiarly *a propos* to my case. My supposition, then, is that in the case I have outlined the change in the arteries, which had been going on for some time, first declared itself at Richfield, when my patient, after an interval of unconsciousness, found herself hemiplegic. This attack was simply the beginning of a certain end. The arterial affection simply progressed to end in a permanent coma—the forerunner of death. Had a post mortem been made I think it probable the main change would have been found at the base, with, perhaps, secondary implication of the left frontal lobe. Whilst there is nothing in the history or the sequel to rule out the presence of a gumma, the above, it seems to me, is a more satisfactory and sufficient explanation. And just here a few words concerning this syphilitic disease of the arteries may not be out of place. To Heubner we are mainly indebted for our knowledge. He has written a monograph on the subject, and a résumé of his views is given by Quincke.¹ The affection has up to the present only been observed in the arteries at the base of the brain, and yet it is probable that arteries in other localities may be diseased in the same way. It is peculiarly a condition of the tertiary period; takes only months for development in contra-distinction to chronic endarteritis, which takes years. Its existence can only be diagnosed during life from the cerebral symptoms, the disease being generally circumscribed, and therefore giving rise to local symptoms. Whilst cure is possible such a result is a rarity.

As to the treatment, when the patient reached my hands it is questionable if the opportune time for any treatment had not nearly passed. These cases of late syphilis should, indeed, be earnest reminders to us of the necessity of prolonged and energetic treatment of any case of syphilis. Without much doubt if my patient had had, during the first half of her diseased period, I will not say proper, for all I know she had rational treatment, but constant treatment, the chances nowadays are that she would have been completely cured. Too often the fault of insufficient treatment, as regards time, must be laid to the door of the patient. But surely the best-intentioned physician has failed in his duty if he does not warn his patient clearly of the shoals ahead in case treatment be not long continued.

A point in the management of the case on which I would lay stress is the large doses of mercury used with apparently no good effect, certainly with little evident bad, for up to eight hours before the end my patient retained strikingly her *embonpoint*, the firmness of her flesh, even of the affected side, and presented but little evidence of cachexia. I believe that with proper care much larger doses of mercury can be administered than is customary, and I also believe that this drug is necessary, when indicated at all, in large dose for complete cure.

And now, in conclusion, what of the man on whose shoulders rests the onus of this woman's death, and whom the child of fourteen has to thank for a blighted existence? It may be that before marriage he had been assured the disease had been routed from his system. That it was not, the case I have reported is sufficient proof. What, then, of the physician who assured the man he was fit to be a husband? Or, rather, since the physician is to be presumed honest

in his opinions, what of our methods, what is our certainty in the assurance that the disease is ever, within reasonable time, completely dethroned? Cases are, of course, numerous where there has been complete cure, and thereafter healthy and fruitful union; but successful cases are apt to be published and cannot, for the reverse reason, be balanced against the unsuccessful. These questions are burning ones, are most important ones, and lead up to another, Should the syphilitic,—he generally becomes so through his own fault,—in our present lack of certainty as to cure in any given case, be allowed to marry at all? If there is no absolute safeguard against the chance of his infecting another being,—who becomes syphilitic not through her own fault,—why not treat him as in olden time the leper was treated? This view is extreme, I well know; it savors, perhaps, too much of antiquity to suit the present non-retrogressive age, but it is well to pause occasionally in our headlong career, and study antiquity for the sake of the sound lessons she can teach us. Till we find a sure specific against this scourge, let us make use of what measure of prevention is within us, strong and determined moral influence. There is no doubt but what the main source of syphilis is prostitution. The results from attempts made in various countries to regulate the social evil were not long since clearly stated by Dr. F. R. Sturgis in a paper read before the New York Academy of Medicine, and from this paper it is evident how little can be hoped for its repression unless public opinion can be educated and arrayed against it. Let the physician start the ball rolling, then; let him, in the first place, make light of no case of syphilis, however mild, and let him, in the second place, bring to bear all the influence within him against the marriage of the tainted with the untainted. If syphilitics must mate let them mate only with syphilitics. To the answer, "But this prevention you would have interfered with the liberty of the subject," I retort, "That is not interfering with the liberty of the subject which punishes him for his license."

A CASE OF SUDDEN DEATH DUE TO HÆMORRHAGE FROM THE HEPATIC VEIN.*

BY ALFRED F. HOLT, M. D.,

Medical Examiner for Middlesex.

J. C., an Englishman, fifty-six years of age, large and strongly built, though slightly hunch-backed, died May 15, 1883. For the last six or seven years of his life he had been engaged in a small kindling wood trade, doing some of the manual labor required by such a business himself. For the ten years before this time he had been a police officer.

Ten or twelve years before his death he began to have severe attacks of colic. These continued to occur at irregular intervals during his life, and for the last six or seven years he was never quite well, although able most of the time to attend to his business. During these years he had consulted a large number of physicians. Most of these pronounced his trouble gallstones, but some of them dyspepsia, and still others some obscure disease of the liver.

Seven days before his death, while in Boston attending to some business, he was suddenly prostrated with a very severe attack of pain in the region of the stom-

¹ Vide Ziemssen, vi., pp. 394 et seq., American edition.

* Read before the Section for Clinical Medicine, Pathology, and Hygiene, of the Suffolk District Medical Society, November 14, 1883.

ach, nausea, and faintness. He was taken to his home in Cambridge in a carriage, and his physician, Dr. Dow, was immediately summoned, who found him suffering from severe pain, vomiting at short intervals, pale, and faint. The pain and faintness continued until evening, he having been taken sick about noon, when the doctor was hastily called again. He found him vomiting blood in the form of very large dark clots. This continued at short intervals for about one hour, when it ceased. A little over three pints of blood was vomited at this time. The pain and faintness continued for three days. Although these symptoms were somewhat relieved by stimulants and opiates, at the end of this time he was again attacked with the vomiting of blood, as before, in the form of very large black clots. This continued at short intervals until nearly two quarts had been ejected, when it suddenly ceased; and after this he was very weak, faint, and nearly pulseless. The pain continued a few hours after this vomiting, when it ceased. Although his mind was clear, he did not rally, but gradually sank, and died forty-eight hours later, or a little less than seven days from the commencement of the sickness. No blood was at any time passed by the rectum.

Autopsy twenty-three hours after death. There was no sign of decomposition. Rigor mortis well marked. Body that of a large, muscular man, and quite fat. There was a thick layer of fat over the abdomen. All of the abdominal organs were imbedded in this tissue. The walls of the chest were expanded in front and at the sides to such an extent as to make quite a deformity; and all the organs of the chest were above the fifth ribs. There was a slight adhesion of the left lung to the chest wall at the top, otherwise the pleurae were everywhere clear, pale, and glistening. Pericardium normal, but on opening this sac the heart was seen to present a noticeably peculiar appearance, the right ventricle being distended so as to make a rounded prominence on its upper part near the auriculo-ventricular junction. The right auricle was also distended. Both of these distensions felt elastic to the touch. On opening this side of the heart there was an escape of a puff of gas, and the walls of the organ immediately collapsed. There was no blood in either of the cavities. The right ventricle was a little dilated, and its walls were slightly thinner than normal. Left side of heart empty. The whole organ was rather large. Its tissues were pale, but of a uniform color. The valves were in every way healthy, and but little blood flowed from the cut ends of the large vessels.

The lungs were very broad and thick, making up in these dimensions what they lacked in length. They were everywhere of a uniform pale color, with darker marbling, except the dependent portions, which were a little reddened. They were also everywhere crepitant, the cut surface showing nothing abnormal, except that the blood-vessels of these organs contained but little blood. The mucous membrane of the bronchi and trachea was pale, and in places smeared over with a little frothy mucus. The spleen was more than twice the usual size. It was fairly firm. Sections showed it of a dark-red or blackish color, and the pulp largely increased. But little blood flowed or could be squeezed from the cut vessels. Both kidneys were imbedded in large masses of fat. They were a little larger and firmer than usual; the capsules slightly adherent. The cut surface showed the cortical

part of a uniform pale red color, and of proportionate thickness. The tubular part was of a bluish tinge, and the blood-vessels could be seen as red lines. These organs contained but little blood. Ureters and bladder healthy. The latter contained a little urine. The stomach was large and flabby, and contained about a pint of liquid food. It, as well as parts of the transverse colon, was firmly adherent to the lower border of the liver. All its tissues were normal in appearance, except that part where it was attached to the liver, which was a little reddened. The pylorus readily admitted the thumb. The duodenum was empty. Opposite the head of the pancreas could be seen the papilla marking the entrance of the common bile duct, as large as the end of the finger, and projecting into the gut. The opening of this duct would readily admit a pencil. Just inside the duct, lying loosely in the canal, was a gall-stone of such a size as to make it a little difficult to force it through the opening into the intestine. The common duct increased in calibre as it approached the liver, until it and the hepatic duct were dilated into a sac or pouch of about two ounces capacity. The walls of this pouch were very thick and hard, and there was a deposit of a dense tissue around them. At the lower side of this sac, near where the gall-bladder entered it, was a cup-shaped depression the size of half a chestnut. When a little water was poured into this a shreddy mass floated up, being attached to the sides and bottom (recent ulceration). On the upper side of this dilated duct, and immediately opposite where the blood-vessels entered the left lobe of the liver, was a similar spot of ulceration, somewhat larger and irregular in outline. On handling a little blood was seen to flow from the bottom of this depression, and an opening was readily found leading directly into one of the vessels entering the left lobe of the liver.

I believed this to be a branch of the hepatic vein, but all of the tissues in this vicinity were bound together in such a confused mass I was not quite certain. The gall-bladder was much thickened, and contracted in such a way as to make its cavity very irregular, and of a capacity of not more than two or three drachms. Its mucous surface had wholly lost its honey-combed appearance. The opening between it and the sack was wide enough to readily admit the finger. Both the gall-bladder and sac when opened contained a little bloody fluid.

The right lobe of the liver was smooth and glistening; rather large, and a little darker colored than usual. The cut surface showed its cellular structure slightly fatty, and its blood-vessels nearly empty. The left lobe of this organ presented a remarkable appearance. It was of a uniform greenish-brown slate color, — smooth but not glistening; and the contrast between it and the right lobe was very striking. It felt firm. The cut surface was of the same uniform greenish-brown color. All appearance of structure had disappeared. A piece of this lobe could readily be broken with the hands; and the fractured surfaces had much the appearance of a nearly dried piece of mud treated in the same way. The larger blood-vessels could be made out in the mass. They were filled with a dryish brown-red material that remained formed when turned out of the vessel, but readily crumbled in the hand into a coarsely granular mass. The main vessels entering this lobe of the liver near the ulceration above described were filled with the same material.

The large intestine contained a little solid and semi-solid yellowish fecal matter. The small intestine was nearly empty, but contained a little of the product of digestion, of a yellowish color. Nowhere in this tube was there anything that looked like blood.

Unquestionably the source of the hæmorrhage was the open blood-vessel supplying the left lobe of the liver; the blood readily finding its way into the duodenum by means of the largely dilated duct and its opening into the intestine, and through the rather open pylorus into the stomach. Why all of the blood should take this course and none of it go down the intestinal canal, as it apparently did not, is one of the points in this case seemingly worthy of discussion.

Of course the gas accumulating in the intestinal canal after death found its way by means of the same open vessel to the right side of the heart.

Hæmatemesis, with the blood coming from such a source, must be exceedingly rare, and so far as I am able to learn this case is unique.

The peculiar condition of the left lobe of the liver I have never seen before. I believe it to have been caused by a complete cutting off of the blood supply, producing a necrosis of the part.

REPORT UPON THE ADULTERATION OF FOODS AND MEDICINES.

BY DR. E. F. DAVENPORT.

ACCORDING to the *Sanitary Engineer* of November 15th the President of France on September 27, 1883, created, in connection with the Ministry of Commerce, a Council of Reference for municipal and departmental laboratories. This council is composed of five members, namely, M. Wurtz, President of the Council of Public Hygiene of France, MM. Pasteur, Brouardel, and Grimaux, members of the same council, and Armand Gautier, member of the Council of Public Health of the Department of the Seine.

The duty of this council is to advise:—

- (1.) On the reports submitted to it by the directors of laboratories, or by municipal and department authorities.
- (2.) On the methods to be employed in laboratories for the examination of articles of food.
- (3.) On standards for purity of articles.
- (4.) On all technical questions connected with the operations of government laboratories and analysts.

This decree is based on a report from the Minister of Commerce, M. Herisson, of which the following is a synopsis: The municipal laboratory of Paris has done such good work in checking adulterations, and so many other cities are following that example, that it becomes the duty of the general government to no longer remain passive, but to encourage and aid such efforts for the prevention of fraud. By the advice of this general council the local laboratories will work with that unity of purpose and uniformity of method without which there can be no efficacious check upon frauds in food. Articles condemned as adulterated at Paris cannot be merchantable in other departments, owing to different methods or standards, and thus honest commerce will be guaranteed as well as public hygiene.

According to the *Analyst* of April, the following decree concerning the prohibition of poisonous colors for

the coloring of certain alimentary substances and articles of food went into operation in Germany on April 1st:—

(1.) The use of poisonous colors for the manufacture of food products or articles of food intended for sale is prohibited. Those which contain the following materials or compositions are considered as poisonous colors within the meaning of this enactment: Antimony (oxide of antimony), arsenic, barium (except sulphate of baryta), lead, chromium (except pure chromic oxide), cadmium, copper, mercury (excepting cinabar), zinc, tin, gamboge, picric acid.

(2.) The preserving and packing of food stuffs or food products intended for sale in wrappers colored with the above cited poisonous colors, or in barrels in which the poisonous colors are so employed that the poisonous coloring matter can pass into the contents of the barrel, is prohibited.

(3.) The employment of the poisonous colors enumerated in Art. 1 is prohibited for the manufacture of playthings, with the exception of varnish and oil paints made of zinc-white and chrome-yellow (chromate of lead).

(4.) The use of colors prepared with arsenic for the manufacture of paper-hangings, as well as that of pigments containing copper prepared with arsenic and of matters containing similar colors for the manufacture of materials of dress, is prohibited.

(5.) The putting on sale, and the sale, wholesale or retail, of food stuffs and food products preserved or packed contrary to the regulations of Arts. 1 and 2, as well as playthings, paper-hangings, and dress materials manufactured in contravention of the directions of Arts. 3 and 4, are prohibited.

In connection with the use of colors containing arsenic, according to the *British Medical Journal*, June 23, 1883, a committee appointed by the National Health Society of Great Britain have reported a special modification of Marsh's test as most suitable for a standard test to be inserted in an Act of Parliament, also special detailed instructions for the carrying out of the Reinsch's test by those preferring this method. These would both insure the absence of more than 0.001 grain of arsenic in sixteen square inches of surface. This, in the case of the Marsh's test, being determined by its failing, when treated as directed, to yield a mirror in a tube one eighth inch internal diameter, sufficient to cut off at any point a black line on a white ground, technically known as thick rule (eight to pica).

Specimen line.

According to the *Boston Journal* of December 5, 1883, in the complaint made by the Massachusetts State Board of Health, Lunacy, and Charity against some wholesale druggists for having violated the Act of 1882 against the adulteration of food and drugs by the sale of a drug which differed in strength, quality, or purity from the United States Pharmacopœia (the standard required when sold under or by a name recognized therein), the court ruled that in accordance with the Act of 1882 the United States Pharmacopœia, Revision of 1880, had become part of the law of the Commonwealth, and the government could proceed under it.

—Scarlet fever is prevalent at Trenton, and diphtheria at New Brunswick, N. J.

Hospital Practice and Clinical Memoranda.

PURPURA FROM QUININE.

BY E. WIGGLESWORTH, M. D.

PATIENT, a respectable woman, aged fifty-two years, was referred to my clinic at the City Hospital by Dr. C. F. Folsom. She had received in his department twelve quinine pills, of one grain each, for neuralgia. She had never suffered before from any disease of the skin.

The first pill was taken the 12th October at four P. M. At five P. M. she noticed upon the left fore-arm a scarlet, non-elevated, irregularly circular patch, about as large as a silver half dollar. This itched and burned and was somewhat painful, especially on pressure. During the day there were three or four chills, with fever between. Fever worse at night, with nausea, "neuralgic" headache, tinnitus aurium, and weakness. More spots like the first appeared during the night, covering the fore-arms and ankles. These all increased in size and in severity of subjective sensations during the following day (13th October), confining her to her bed. No new spots, however, appeared after the night of the 12th to 13th inst.

Not attributing the eruption to her medicine she continued her pills, taking the last one after dinner Wednesday, 17th inst. From the 15th to the 17th all the symptoms were at their height.

Wednesday (17th) she began to feel easier, and has since grown steadily better.

Friday, 19th. Complaints of weakness. The spots are well marked, but not swollen, hæmorrhagic patches, not disappearing under pressure.

October 26th. Patches dull in color, desquamating slightly, with some itching.

October 29th. Desquamation more marked; color, a deep brown. No subjective sensations unless the spot is struck.

November 2d. Patches have scaled and the color has faded, although still evident.

November 9th. Patient called to report recovery. No further trouble of any kind, and merely a slight pigmentation marking the site of the patches.

Treatment. Hygiene; tonics, namely, iron, and, *experienti gratiâ*, "celerina," from which she reported benefit. Externally astringent ointments, zinc, etc.

Reports of Societies.

BOSTON MEDICO-PSYCHOLOGICAL SOCIETY.

WALTER CHANNING, M. D., SECRETARY.

THE Society held its twentieth regular meeting on the evening of November 1st at the house of Dr. Jelly, DR. COWLES occupying the chair.

DR. S. G. WEBBER read the paper of the evening, entitled

TWO CASES OF PARAPHASIA, ONE WITH AUTOPSY.

In the discussion following the reading of the paper DR. DENNY said:—

The case of aphasia reported, which came under my care at the City Hospital shortly after the beginning of the trouble, interested me from the fact that there

was (1) no evidence of there having been any right hemiplegia, as is usual; (2) that the aphasia and agraphia rapidly, and in equal proportion, showed evidences of improvement until both nearly or quite disappeared before discharge from the hospital; (3) that there was no hemiopia and no word-blindness, while the lesion discovered after death is located in the inferior parietal lobe. But three cases of word-blindness with autopsies are on record, and in all these there were lesions of the inferior parietal lobe, and in two there was lateral hemiopia;¹ (4) the lesion found did not explain, from its location, the cause of aphasia.

From the comparatively rapid restitution of the faculty of speech while the lesion remained, which probably occurred simultaneously therewith, we may assume that the aphasia was due to some disturbance of circulation temporarily affecting the integrity of the functions of the third frontal convolution or of the fossa Sylvii, which occurred at the same time, and disappeared from any local point of view thereafter. It has been said that agraphia associated with aphasia is evidence of a considerable mental impairment, and I was interested in studying the degree of mental capacity to note that while there was some failure of mental power, probably, yet it was not sufficiently pronounced to have interfered with the validity of a will nor a contract.

The first patient had rather that form of aphasia which Kussmaul calls paraphasia, not complete amnesic aphasia. There is no autopsy recorded, that I am aware of, where that was so prominent a symptom as it was in this case, and where so few other symptoms were present. Wernicke locates the lesion which will cause this form of disturbance in the commissural fibres uniting the sensory speech centres with the psychic speech centre. The lesion in the present case might well have exerted an indirect influence upon these fibres to temporarily inhibit their functioning. The lesion producing word-blindness needs to be more accurately localized. It is certain that that centre was not directly implicated, as the power of reading returned if it had ever been lost.

In the second case there was word-blindness and paraphasia, but no word-deafness. An autopsy would have been most interesting.

PROCEEDINGS OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.²

ALBERT N. BLODGETT, M. D., SECRETARY.

SUDDEN DEATH DUE TO HÆMORRHAGE FROM THE HEPATIC VEIN.

DR. A. F. HOLT, Medical Examiner for Middlesex, presented a paper³ upon a remarkable condition found at the judicial autopsy of a patient dying under peculiar circumstances. The cause of death here reported, namely, hæmorrhage from the hepatic vein, has not, so far as known, been previously observed. The case occurred in the practice of Dr. Dow, of Cambridge, from

¹ Einige seltene Formen von Wortblindheit (Cécité verbal) aus Prof. Charcot's Klinik, Emanuel Heczel, Wiener med. Presse, No. 26, 1883.

² Concluded from page 566.

³ See page 584 of this number of the JOURNAL.

whose notes the clinical history as here given has been copied.

DR. F. A. HARRIS, Medical Examiner for Suffolk, said that the strange and heretofore unknown occurrence recorded by Dr. Holt is valuable in making us acquainted with a new causation for sudden death. The medical examiner is required to investigate all cases of death of a sudden or suspicious character, and it no doubt may happen that cases are returned as due to disease of the heart, no other ascertainable lesion existing, which may be due to some cause not hitherto reported and entirely unknown. In many cases some obscure disease might easily be quite overlooked. Among such causes is aneurism, which, even when of small size, may at times obstruct the nutrition or disturb, and at length entirely suspend, the function of important organs. In one case, an unsuspected small aneurism of the internal carotid caused obscure cerebral symptoms, and finally death, from pressure upon one of the pneumogastric nerves. Aneurism of the arch of the aorta may be suspected from the occurrence of disorders of the vocal apparatus in the larynx, not due to any organic local disease, when the existence of aneurism is not evident from any other symptom. In such cases the existing disease may be so slight that it may escape observation at the autopsy, and the death of the patient be charged to some other cause. The medical examiner is required to give a cause of death in all suspected cases, the law requiring him to ascertain the manner by which the person met his death. For this reason, if for no other, all cases of death from rare diseases should be reported, for the benefit of State and local Boards of Health, as well as for statistical and other purposes.

DR. FITZ considered the paper extremely interesting, and was glad to have heard the report of so rare a case. He said he had never seen anything of a similar nature in his personal experience. Gall-stones may occasionally become a cause of ulceration of the gall-bladder, and secondarily lead to much further mischief. The reported condition of the liver is very remarkable. Such a change is occasionally observed in the lung as a wedge-shaped necrosis of a part of the pulmonary structure due to embolism of some vessel. The necrosed portion then quickly becomes the seat of gangrene, and generally goes on to a fatal termination. The presence of gas in the heart is interesting. The opinion of Dr. Holt that the gas was formed from decomposition after death might be criticised, as it might quite as easily enter the venous channels during life.

DR. WEBBER asked if gas, entering the circulation before death, would not be evident from a frothy condition of the blood on opening the heart.

DR. FITZ replied that while this is often the case it is not necessarily so. It may escape as a free gas. Atmospheric or gas embolism is sometimes observed in other parts, especially in the lungs.

DR. PRINCE observed that pancreatic apoplexy¹ may be accompanied by many of the symptoms mentioned in this paper, and quite generally vomiting occurs.

DR. CHURCH, of Cambridge, presented the following

NOTES OF A PECULIAR CASE IN WHICH THE AUTOPSY SHOWED CONGENITAL ABSENCE OF THE LEFT KIDNEY.

On Tuesday A. M., November 6th, I was called to

attend Mrs. L., a Swede, in confinement. On arriving at her house I was shown into a room containing a bed, and upon it lay a well-dressed woman, apparently forty years of age; presuming her to be Mrs. L. I approached the bed, and made the inquiry if she was the person to whom I was called, to which she responded in the negative, saying that she was a friend of Mrs. L.'s, and had arrived from Vermont the evening previous, and had not felt well since her arrival. She complained of pain in the stomach and back, with slight headache, but thought she had taken cold, and a little rest would suffice to restore her to usual health. I then passed on to attend Mrs. L. in an adjoining room, and did not see Miss A. until three or four o'clock in the afternoon, when I obtained the following history:—

Was born in Sweden; was forty-five years old; came to this country two years ago; had always been well excepting "slight touches" of dyspepsia and occasional sharp pains in the epigastrium. Menopause fully established before she left Sweden. Had worked as a domestic in a farmer's family in Vermont for nearly two years. Said that the bowels were regular, and appetite usually good. Never used stimulants or narcotics.

When asked if she had not better have some medicine, she said No, as she thought rest and diet would be all that was necessary. Saw her on the following morning while visiting Mrs. L. Said she had not slept during the previous night. Bowels and bladder had been evacuated during the night, but the pain in the back and stomach had not subsided, and she had vomited twice during the morning, and had an attack of epistaxis and severe headache. The tongue was very dry, and in the centre covered with a thick, brown incrustation; some sore throat. Examination of the chest gave negative results; the only peculiar feature was the feebleness of the heart sounds. Pulse 88; temperature 96.5° F.; respiration normal; slight tenderness on pressure in the right hypochondrium. Warm applications and stimulants were ordered, and at noon she got up, went into the kitchen, and drank some milk and tea. Did not see the patient again until Thursday A. M., at nine o'clock, when I found her comatose. I was told by the people in the house she had slept all night. At the time of visit the respirations were heavy, tongue and mouth as dry as parchment, and mouth and throat full of a mixture of dried blood and saliva; pulse 88; temperature 95° F.; pupils dilated; marked pallor, and a peculiar pinched expression of the face. Feeling that the case would prove fatal, and knowing that the patient had no relatives or friends in this country, I asked City Physician Bryant to see her. Pulse at time of visit, 12.30 P. M., 90; respiration normal; temperature 95° F.; patient profoundly comatose. At five P. M. she became pulseless, and expired at nine P. M.

Examination of the urine gave the following results: color pale; reaction neutral; specific gravity 1010; large trace of albumen; urea slightly diminished; phosphates and chlorides diminished. Microscopic examination showed triple phosphates, no pus or blood, a few degenerated renal epithelium cells, but *no casts or fat*.

Feeling that, either from imperfect memory or inability to understand or express herself in our language, the history given me by the patient was incorrect, I wrote her employers at Williamstown, Vt., and obtained the following additional history:—

¹ A report of two cases, with references to fourteen other cases, was read before this Section, May 6, 1882.

First. That she had suffered much from what had been called by a resident physician dyspepsia.

Second. That one year ago she had an illness of five weeks. Diagnosis, "ulceration of the lung and slow fever." That previous to coming into their employ she had visited the Massachusetts General Hospital, for nausea and suppression of menses, and was thought to be pregnant.

Third. During the last year, though her appetite was good, she complained of feeling weak, of having headaches and frequent attacks of severe epigastric pains and cramps in the lower limbs, also of some dizziness.

Fourth. That large quantities of urine had been voided, especially during the night, for a long time.

Fifth. That when she arrived at Mr. L.'s on Monday night she complained of feeling very dizzy, and trembled violently.

Sixth. That for the past eight or nine months the patient had complained of sleepiness during the day, and imperfect vision.

The autopsy was made by Medical Examiner A. F. Holt, Saturday morning, November 10th, to whom I am indebted for the following report:—

"The body examined was that of a Swedish woman forty-five years of age. The heart was enlarged, particularly the left side. The left lung was adherent throughout. Spleen normal in size and appearance. Left suprarenal capsule in its usual position, but a little larger than normal. No left kidney, renal artery, or ureter could be found, or anything to indicate that they had ever existed. The right kidney is the one here shown. It is very small, not larger than a large hen's egg, and shaped much like one. The whole organ feels firm and rather hard. The capsule is much thickened and adherent. The cut surface, when removed, was of a uniform grayish color, with darker mottlings. The line between the cortical and tubular parts could not be made out at that time; now, as it has been in dilute alcohol for a day or two, it can be distinguished. The greater part of the organ seems to be made up of the cortical portion. The whole organ, without doubt, has undergone some marked change, probably interstitial nephritis, but of this I am not certain, as no microscopic examination has been made.

"The liver was a little larger than usual. Stomach and intestines apparently healthy

"In my experience in making autopsies, only in one other case have I found but a single kidney; this was in a man, sixty-five years of age, who died of cancer of the stomach. In that case the single kidney was very large and healthy, and, as in the present case, it was the left kidney which was wanting. I believe that both of these cases were congenital."

Dr. Church also exhibited the vermiform appendix of a patient who died from perityphlitis and peritonitis, and in which the cause of the disease was found to be an ordinary brass pin, which had been swallowed, had passed through the stomach, duodenum, and the entire length of the small intestine, and had entered the vermiform appendix, head downward, where it had awakened a violent inflammation with the subsequent fatal result.¹

Adjourned at 10.40 P. M.

NEW YORK ACADEMY OF MEDICINE.

THE PREVENTION AND TREATMENT OF PUERPERAL SEPTICÆMIA.

At a meeting of the Academy of Medicine held December 6th, after the usual routine business and the nomination of officers, Dr. T. GAILLARD THOMAS read a paper on the above subject. Having made a forcible introduction, in which he urged the necessity of such a paper at the present time, he went on to say that during the last quarter of a century great advances had been made in the treatment of febrile conditions incident to the puerperium. Long before this time the communicability of puerperal disease was recognized, but the subject had assumed more importance since the introduction of the germ theory. Ever since the time of Hippocrates, more than two thousand years ago, the profession had been struggling to master the hydra-headed monster, and it was only now that it was beginning to find its way out of the darkness in which it had hitherto been working. We were now at last beginning to understand how to treat puerperal septicæmia.

Dr. Thomas then described some of the characteristics of the parturient condition. Among these was the great excess of fibrine which the blood contained, thus presenting a marked tendency to embolic obstructions and to the development of sepsis and zymosis. Secondly, the nervous system was in a state of plus excitability, so that a small amount of urinary poisoning produced convulsions, and any mental disturbance was liable to result in violent mania, while derangements of digestion that would scarcely occasion the slightest inconvenience at ordinary times became a very serious matter. He then described the condition of the uterus and its appendages in the puerperal state, alluding particularly to the small rents or abrasions that were liable to be caused by the process of delivery in the cervix, the vagina, and the vulva, and over which flowed, even in perfectly natural cases, the ichorous and irritating lochial discharge. Ordinarily, however, this gave rise to no unpleasant consequences, and a fatal result was the very rare exception.

Then describing the symptoms of the onset of an attack of puerperal septicæmia, he said that not uncommonly the attending physician consoled himself with the idea that the trouble was only malaria or "milk fever," and even if he recognized the true nature of the affection he was too apt to postpone the adoption of energetic measures until the disease had advanced to such a stage that its progress could not be arrested. Were this the case we should find within a week that parenchymatous metritis, lymphangitis, phlebitis, peritonitis, endocarditis, pneumonitis, pleuritis, or other inflammatory process due to the septicæmia, had become fully developed, and that finally the patient would die from high temperature or exhaustion.

It was difficult to give an exact definition of puerperal fever, Dr. Thomas continued, but he was unwilling to adopt any which did not acknowledge the affection to be septicæmia, no matter what form it assumed. The cause of the disease was absorption of a poison by solution of continuity in the genital tract. As long ago as 1871 Hervieux had formulated his opinion in the following words: "I believe in the multiplicity of puerperal diseases. I believe in their common origin from puerperal poison." He also quoted from the

¹ The above case was reported in full in the JOURNAL, vol. cix., p. 269.

report of a distinguished committee of the Berlin Obstetrical Society.

As to the matter of nomenclature, the Dublin School of Obstetrics had recently proposed the word "metria" instead of puerperal fever, but he did not consider that it was in any way better than the old term. On the other hand the term puerperal septicæmia conveyed a clear and definite idea of the nature of the affection, and in spite of the fact that complications were so frequent he thought it should be adopted. It had also been recommended by Barnes, though the latter had insisted that it should be adopted only with the understanding that the term did not imply a distinct and specific poison. Personally he believed that there was a specific poison.

Although many investigations were at present being made in regard to the subject, it was impossible as yet to state the exact nature of this poison. But notwithstanding the fact that this remained unknown we did know that such a poison existed, and that it could be introduced into the system in only two ways, namely, through the atmosphere and by contact of the physician's or nurse's fingers or of clothing or bed-covers with the genital tract.

It was only in regard to the management of cases in private practice that he proposed to speak, as in all well-regulated lying-in hospitals positive rules for the prevention of puerperal septicæmia had long been adopted. In private obstetrical practice, however, a laxity prevailed that was nearly akin to criminality. The following rules were then suggested for the prophylaxis of puerperal septicæmia:—

(1.) The room should be cleared of every unnecessary article and of all curtains and upholstery as far as possible, after which the floor, walls, ceiling, and furniture should be well sprinkled with a ten per cent. solution of carbolic acid or a solution of mercuric bichloride of the strength of one part to one thousand of water.

(2.) The nurse and physician should be scrupulously clean about their persons, and, if either had been exposed to the poison of scarlatina or other septic influence within fourteen days, should use such a disinfecting wash as a saturated solution of boracic acid.

(3.) As labor sets in, the nurse, having cleansed her hands with a stiff nail-brush, should make a warm vaginal injection of a solution of mercuric bichloride or other antiseptic, and should repeat it every four hours.

(4.) Both the nurse and physician should use a solution of mercuric bichloride (1 to 1000) upon their hands and every instrument or utensil employed during labor.

(5.) The third stage should be efficiently produced, and ergot, in moderate doses, should be subsequently kept up three times a day for at least a week.

(6.) At the end of labor the physician, taking nothing for granted, should make an examination of the genitals, and if there has been a rupture of the perinæum should close it up with sutures at once. If any slight solutions of continuity are discovered they should be wiped with a linen cloth and then treated with persulphate of iron and carbolic acid, after which they should be again wiped with a cloth and painted with gutta-percha collodion.

(7.) In six or eight hours a warm antiseptic vaginal injection should be made, and a suppository containing from three to five grains of iodoform should be placed under the os uteri. The injection should be repeated every eight hours.

(8.) The suppositories should be repeated every two or three hours, and kept up for at least ten days.

(9.) When catheterization is necessary, a new gum elastic catheter, which has first been dipped in an antiseptic solution, should be employed.

(10.) The physician should convince himself that the nurse has the ability to use suppositories, syringe, and catheter as required.

It was clear, Dr. Thomas continued, that all this tended to increase the importance of the process of parturition, so that as the opinions became more widely accepted a woman who was about to bring forth would be regarded exactly in the light of a patient about to undergo a capital operation. Having strongly condemned the use of intra-uterine injections as a prophylactic, except after very severe operations within the uterus, when the occurrence of septicæmia was almost certain, he proceeded to call attention more particularly to the early symptoms of the disease and the necessity for prompt interference on the part of the physician. The treatment which he recommended was as follows:—

(1.) The hypodermic injection of morphia to allay nervous irritability and afford relief from pain. The injection, as a rule, to be repeated every six or eight hours. A new needle to be employed, and after use to be thoroughly washed with soap and water, and dipped in a solution of mercuric bichloride.

(2.) Intra-uterine injections of warm water containing mercuric bichloride, in the strength of one part to two thousand, by means of Chamberlain's glass tube, modified by reducing the number of waste-holes, or the metallic tube devised by Dr. George H. Lyman, of Boston. In some cases where it was supposed that portions of the placenta were retained, chloroform was to be given, and the uterus cleared out with the fingers. The dangers of the intra-uterine injections were pointed out to be, entrance of air into the uterine sinuses, hæmorrhage, the carrying of poison into the circulation through the open sinuses, pain, shock, or convulsions from the effect upon the nervous system, and peritonitis from the entrance of the fluid into the peritonæum through the Fallopian tubes. The injections were always to be administered with great care by the physician himself, the tube being passed fully up to the fundus, and it was important that neither the os internum or os externum should be so completely filled by the tube that the fluid could not find free exit. Ergot and bisulphate of iron were always to be kept at hand in case of the dislodgement of a thrombus. A number of deaths had been reported as due to intra-uterine injections, and Dr. Thomas had met with one fatal case in his own experience. In mild cases the injections were to be given every five hours and in others every three hours, while in bad cases they were required every hour. Many preferred the steady stream of the fountain syringe, but he was convinced that the interrupted stream of the Davidson or Higginson syringe was much more serviceable. Some had adopted the plan of continuous irrigation, but this he believed to be entirely inadequate, because the germicide fluid could not by this means be brought in contact with the whole endometrium. In some bad cases, however, it was well to resort to this, and then, in addition, employ the intermittent stream once in three hours.

(3.) The reduction of temperature. High temperature was one of the immediate factors of a fatal issue, and in order to control it he had formerly relied on

Kibbie's cot. Now, however, he employed Townsend's rubber coil, a mat composed of a long rubber tube coiled in circles upon itself, which was placed upon the abdomen, extending from the symphysis pubis to the ensiform cartilage, and through which a constant stream of ice water was passed. By means of this a temperature of 104° F. could be reduced to 100° F., and maintained at this point indefinitely. Some physicians had expressed the belief that it would give rise to pneumonia or pleurisy; but he had never seen any such result, and the coil was constantly in use at the Woman's Hospital after laparotomy. Its prolonged use was essential, and its removal from the body for even a single hour was sometimes quite detrimental. If hot water bottles were kept applied to the soles of the patient's feet, not the slightest bad results were to be apprehended from its employment.

(4.) The use of febrifuges such as quinine, Warburg's tincture, and salicylate of soda.

(5.) An ample milk diet, supplemented by animal broths.

(6.) Efficient and abundant assistance. It was essential that there should be both a day nurse and a night nurse, and that a physician should be in the house all the time. With simply one physician and one nurse the treatment could not be carried out successfully. If carbolic acid were employed for the intra-uterine injections a two per cent. or two and a half per cent. solution was recommended.

DR. W. M. POLK said that as regards treatment Dr. Thomas had left but little to be said. In the matter of pathology, however, he thought it would perhaps have been better if he had planted himself more squarely on the position that puerperal fever was identical with surgical pyæmia and septicæmia. This was his own opinion, and if we were to adopt the measures so forcibly set forth in the paper he believed that it was necessary to take this position. It was only in the domain of ætiology that those who opposed this view found ground for support. As regards treatment, the principles of Listerism as laid down by Lister and his followers, and advocated on the present occasion by Dr. Thomas, entirely covered the ground. He would merely add that in this city, where there was so much bad drainage, the question of pure air formed a very important one in this connection. Not infrequently the lesion giving rise to trouble was located in the cervix, and the stream of the intra-uterine injection was not sufficiently powerful to separate the agglutinated surfaces. His plan was to make a thorough inspection of the vagina and cervix by means of Sims's speculum, and, in case of any lesion being discovered, to apply a strong solution of carbolic acid or other antiseptic directly to the spot. To the interior of the uterus he sometimes applied a two per cent. solution of carbolic acid on borated cotton, if no solution of continuity were found without; and when there was reason to suspect that any part of the placenta was retained he was in the habit of using Skene's broad curette.

DR. J. B. HUNTER spoke of the difficulties in carrying out Dr. Thomas's plan of treatment, especially when the patient was in moderate circumstances. In order to cause as little disturbance as possible, he preferred to use a bed-pan in making intra-uterine injections, rather than have the patient moved to the edge of the bed, with her feet resting on chairs, as recommended in the paper. He objected to Chamberlain's tube on account of the probability of the fluids not

reaching the fundus through it, and had had a tube made about half the size of this, with orifices only at the extremity. The mouth of the uterus he had found to contract very considerably after two or three hours, and it was sometimes necessary to dilate it. Mott's double catheter, he thought, was a very good instrument to employ in making intra-uterine injections. As to the effect of the injections, he did not believe there was much danger of causing shock, but once or twice he had noticed them to be followed by a slight chill, a fact which he attributed to the water employed not being quite warm enough. He narrated one case in which septicæmia had occurred as late as the seventh week. When he was called in the patient was moribund, and the temperature ranged from 103° F. to 105° F. The physician in attendance was opposed to resorting to intra-uterine injections, but it was determined to resort to them. At first they seemed to have very little effect; but they were persevered in, and at the end of twenty-four hours the temperature was about normal. They were kept up for three days longer, and the patient recovered. In simple septicæmia he did not believe in the use of the coil, but in peritonitis, as after the operation of laparotomy, he had the strongest faith in it. The septicæmia might be of a very serious nature, and yet the temperature be comparatively low.

After a few remarks by DR. PARTRIDGE, the President, DR. BARKER, proposed, in view of the lateness of the hour, the importance of the subject, and the number who wished to speak upon it, that the first meeting in February should be set apart for the further discussion of the paper.

Recent Literature.

The Pathology, Diagnosis, and Treatment of the Diseases of Women. By GRAILLY HEWITT, M. D. Edited, with notes and additions, by HARRY MARION SIMS, M. D. New York: Bermingham & Co. 1883.

This work is the American reprint from the fourth revised and enlarged London edition. It is ten years since the last edition appeared, and the valuable experience of those years is made good use of by the author. It has in no wise shaken his well-known views of uterine pathology; on the contrary they have been strengthened, and not only does he still look upon uterine displacements as the predominant cause of uterine disease, but he alleges as the predisposing cause errors of nutrition. The experience of the last ten years has served to confirm these views, and they are very fully developed in this edition.

Grailly Hewitt's work is too well known to need any detailed criticism. This present edition has been thoroughly rewritten, and considerable new material added. A new chapter on Hysteria and one on Vomiting in Pregnancy explain both conditions in accordance with the author's well-known mechanical pathology. This is not the place to discuss the author's views at length. We would, however, say that the value of the work is to our minds impaired by the predominance he gives to displacements and distortions of the uterus as a cause of uterine disease. In his zeal he goes too far, and fails to give other factors their just weight.

The book, however, is an interesting one, full of suggestion, and well worthy careful reading. Its value is enhanced by the good work done by the American editor, who, in a series of notes incorporated in the text, has very happily supplemented some portions of the original work which were rather meagrely treated, or has quite as happily corrected certain erroneous views and statements. We cannot help wishing that the English edition might have had the benefit of these valuable notes.

The book itself, while not unexceptionable in the matter of paper, type, illustrations, and binding, is very fairly gotten out.

Insanity Considered in its Medico-Legal Relations.

By T. R. BUCKHAM, A. M., M. D. Philadelphia: J. B. Lippincott & Co. 1883.

This volume of 250 pages was written principally for the purpose of pointing out the "pernicious uncertainty of verdicts in insanity trials."

Chapter one gives a variety of definitions of insanity, of courts and various authors, and points out their lack of harmony. Chapter two descants on an original theory of the writer called the "Physical Media Theory." This theory, like the "Metaphysical Theory," regards the mind as a distinct, intangible, incorporeal entity, not dependent upon the body for its existence; . . . it recognizes the most intimate relations between mind and body, . . . and holds that the mind is *wholly dependent* for the manifestations of its operations on certain organs of the body which we designate "*physical media*." Nearly forty pages of miscellaneous quotations and discussions are taken up in elucidating this theory, which is at last established to the author's entire satisfaction and the reviewer's utter stupefaction. The chapter ends with the very wise conclusion, that "Insanity being the result of physical disease, it is a matter of fact to be determined by medical experts, not a matter of law to be decided by legal tests and maxims."

Chapter five, which is a very long one, is given up to Experts, and an appendix is devoted to the consideration of Judges' Opinions.

The style of the writer is rather too diffuse, and he wanders through a good many pastures that are anything but new, but he finds some pabulum which, if not always fresh and green, will at least do to ruminate over.

Students' Manual of Diseases of the Nose and Throat.

A Digest, descriptive of the more commonly seen Diseases of the Upper Air-tract, with the Methods of their Treatment. By J. M. W. KITCHEN, M. D., Assistant Surgeon to the Metropolitan Throat Hospital. New York: G. P. Putnam's Sons. 1883.

This elementary little book, 124 pages 16mo, is a compilation of some of the existing knowledge of the diseases of the nose and throat. It was written, the author tells us in the introduction, with the thought that it "might be of service to the over-worked student, and even be of value as a handy book for quick reference to the general practitioner." We question whether it is for the ultimate advantage of students to attempt to acquire medical knowledge by these short cuts; but if there be a demand for them, this slender volume will be found fully up to the average.

Practical Histology and Pathology. By HENRAGE GIBBES, M. D., Lecturer on Physiology and Histology in the Medical School of Westminster Hospital. Second edition. Philadelphia: P. Blakiston, Son, & Co. 1883. 154 pages.

Dr. Gibbes is well known as a preparer of histological objects, and this book bears the impress of one who has a thorough practical knowledge of the subject about which he writes. It is almost entirely devoted to the best manner of preparing specimens, and gives but brief description of the objects themselves. The first part of the book treats of the normal tissues, telling from what animal and part they are to be best obtained, preserved, and stained. The second part is largely given up to the methods of staining bacteria, especially the bacillus tuberculosis. All who are interested in such work will find many valuable suggestions on the use of aniline colors for double and treble coloring, to which the author has given much attention. The book deserves a place in the library of every advanced student of the microscope.

Manual of General Medicinal Technology, including Prescription Writing. By EDWARD CURTIS, A. M., M. D., etc. New York: William Wood & Co. 1883. Wood's Pocket Manuals. Pages viii., 234.

This pleasantly written little book is less technical and mathematical than the name (to which it is hardly large enough to be entitled) would lead us to expect, and can hardly fail to be interesting as well as profitable to the medical student who reads it.

It contains an excellent chapter upon the Forms of Medicines, preparations, etc. A good one upon the Prescribing of Medicines, and a few pages upon Quantities of Medicines, namely, weights and measures. These comprise about three fourths of the book, and are followed by Modes of Medication; The Introduction of Medicine into the Various Cavities and Tissues of the Body, and Dosage. These last chapters might profitably have been much more full.

An Ethical Symposium, being a Series of Papers Concerning Medical Ethics and Etiquette, from the Liberal Stand-point. By DRs. POST, ELY, VANDERPOEL, PILCHER, HUN, WEY, AGNEW, etc., etc. With an Appendix. New York: G. P. Putnam's Sons. 1883.

Those who desire to know what the advocates of "No-Code" in New York think, and why they think it, will wish to read this book.

The Treatment of Wounds as Based on Evolutionary Laws. By C. PITFIELD MITCHELL. New York: J. H. Vail & Co. 1883.

In this little treatise is set forth, in a strained imitation of philosophical language, the idea that by the law of evolution the tissues when healthy must of necessity be adapted to safe and speedy healing in normal surroundings of air, etc. The author advocates the use of dry dressings. He regards the use of antiseptics as meddlesome interference with nature. Verily the closest naturalist still lives.

Medical and Surgical Journal.

THURSDAY, DECEMBER 20, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number: \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

INSANITY AND MURDER. TWO TRIALS.

THE CASE OF FREEMAN, THE INSANE KILLER OF HIS CHILD.

On the first day of May last Charles F. Freeman was brought before Judge Colburn, of the Supreme Court, on motion of his counsel, for his release from the Danvers Lunatic Hospital, where he had been for a little over three years. Although indicted by the Grand Jury for the murder of his daughter, May 1, 1879, under the influence of the delusion that, like Abraham, he had been commanded by the Lord to sacrifice his beloved child, he was declared by the Court unable to plead understandingly by reason of insanity, and sent to the insane asylum to await the further orders of the court. The progress of his cure was well described by Dr. W. B. Goldsmith, medical superintendent of the hospital, who testified that when he first went as superintendent to Danvers, in March, 1881, and met Freeman, the latter was physically without any peculiarity. He was quite composed, but he had at that time insane delusions of a religious type. He believed even then that he was specially favored by the Lord, from whom he had had a direct revelation. He regarded himself as the Christ of his age, and regarded his appearance at this epoch as an important event in religious history, and in fulfillment of a prophecy. He had no remorse whatever for his act, but sometimes doubted whether he had not been inspired by the devil instead of by a beneficent Deity. Later on he began to doubt whether he was really insane or the victim of demoniacal possession. About a year ago he came to the conclusion, especially after watching his fellow-patients, that he was, or had been, insane. Gradually all his delusions left him and he became quite convalescent. At no time since last summer would witness have signed a certificate that he was insane. For ten months he had had full liberty of the hospital grounds on parole. There was no need to watch him as an insane man, for he was now fully recovered. To say whether there was any danger of a relapse would be purely guess-work. Apparently there was not, but he was now of the same mental constitution which had previously predisposed him to insanity. Witness did not believe there was any reasonable danger in allowing him to go free. In reply to Attorney-General Sherman the witness said that persons in a state of delusion often accepted

dreams as divine revelations. Freeman was always sorry for the act. He was sorry when he was insane, but then he regarded it as a necessity. When he recovered he did not feel responsible for the act, as he knew that he was insane at the time. In that sense he felt no remorse, but only sorrow. Freeman had informed witness that he had entirely changed his religious views. The last thing he would do would be to return to Pocasset and mix with his old associates in the religious excitement.

Dr. Gorton, assistant physician at the asylum, and Dr. C. F. Folsom testified to essentially the same opinion. Dr. Park, superintendent of the Worcester Lunatic Hospital, and Medical Examiner Munsell gave evidence that they considered Freeman no longer insane. Judge Colburn said that there was no doubt of the fact that Freeman had recovered; but he did not think that he had any power to release him upon his own recognizance, as desired by his counsel, or upon bail, as agreed to by the Attorney-General. Freeman was thereupon remanded to jail.

December 5th Freeman was brought to trial before a jury. After a few witnesses' testimony to the fact of the homicide, Dr. C. F. Folsom, Dr. J. P. Brown, medical superintendent of the Taunton Lunatic Hospital, Dr. J. H. Denny, Dr. Peter Pineo, and Medical Examiner Munsell, testified that Freeman was then, in their opinion, insane. The question of his present mental condition was not touched upon. The verdict of "not guilty by reason of insanity" was brought in by the jury, and Chief Justice Morton sent him to the Danvers Lunatic Hospital for life, in accordance with the Massachusetts law of 1873, that, whenever a person is found not guilty of homicide by reason of insanity, the jury shall so state in their verdict, and the judge shall commit the prisoner for life to an insane asylum, from which he can be discharged only by death or by pardon at the hands of the Governor and Council.

There are now, beside Freeman, three persons in our asylums for life, found not guilty of homicide by reason of insanity, — a man who killed his wife under the influence of the delusion that she was plotting to kill him, and while far enough advanced in his disease to have become slightly demented; the boy who killed his comrade in Somerville, in whom the evidence of insanity was somewhat obscure; and a young woman who drowned, and perhaps also strangled, her illegitimate child. Probably all persons familiar with criminals and with mental disease, after making a personal examination of these three individuals, would agree that it is not now safe, and that it probably never will be safe, to discharge either one, unless many years hence when dementia may have supervened.

In Freeman's case Drs. Goldsmith, Gorton, and Folsom have stated their conviction that there is not much probability of a relapse or a recurrent attack, and that they see no unreasonable risk to society from the chance of his being again insane and committing another crime.

Dr. Goldsmith, however, it must be borne in mind,

had previously stated that it would be purely guess-work to say whether there was any danger of a relapse; and in such a case as Freeman's we are not disposed to dissent from such a statement, but rather to approve it, and to remember "that he has still the same mental constitution which previously predisposed him to insanity."

We do not understand that the medical experts have expressed any opinion as to the effect on other persons disposed to commit crime of pardoning or refusing to pardon Freeman. Indeed that is rather a question for the officers of the law than for the doctors. But, if we expect society to respect the opinions of special students of mental disease and to be guided by them in its treatment of insane criminals, the utmost caution and solemnity should attach to a verdict of "not guilty by reason of insanity," and to a judgment of commitment for life to an asylum. The pardoning power should intervene with at least as little indiscretion as is now shown toward the ordinary criminal.

We have lately called attention editorially to what we termed "judicial murders" in England, the following account exhibits, on the part of the defense, if we may trust the report of the trial therein given, the possible dangers of opposite tendencies, and the case of Montgomery is opportune in contrast to that of Freeman.

THE CASE OF MONTGOMERY, THE MURDERER OF HIS CHILD.

Since the memorable Andrews trial, in which the sentence to the State Prison for life was, in our opinion, properly passed, there has not been, so far as we can recollect, a single case of the plea of temporary insanity or transitory mania having been entered for a murderer in this State until last week, at Northampton, in behalf of Montgomery, who killed his child December 26, 1882, at the house of his father-in-law, Mr. Marsh.

Montgomery had been married for about seven years, and had two children, Eva and George. He had not lived with his wife for some time, but he came to Pelham early in November with Constable Burnett, and demanded his children, saying that he had heard that his wife was living with Irving Carry and other men. This was emphatically denied, and the father-in-law told him that he could not take the children unless it was over his dead body. At that time Montgomery seemed very much excited, and put his hand upon his hip-pocket. Mr. Marsh told him to draw his pistol if he wanted to, but Mrs. Marsh interfered and pacified the men, and it was agreed that the matter should be dropped. Montgomery stayed two or three days, and came again just before Christmas, bringing presents to his wife and children. Tuesday morning he tried to prevail upon his wife to go and live with him again, and, on her refusal, he went to his overcoat, hanging on the wall, and, muttering "All right," stepped to the outer door where his little boy was playing on the sled. Another boy called, "Georgie," but he said, "I want to kiss papa first," and just then the father fired the fatal shot. Then he ran into the house, and was caught by Mr. Marsh. Mrs. Marsh got the clothes-line to tie him up with. When this was done Montgomery cried out, "Oh God, forgive me for what I have done," and again, in a few minutes, when charged with his crime, he said, "God knows I haven't killed my boy, and if I have I don't know it." He only wounded the other child, and was quite unsuccessful in his attempt to kill his wife. At one time Montgomery had trouble with Mr. Marsh, and drew a knife on him. He loved his children, and he very rarely punished either of them. Mrs. Marsh spoke of her daughter's intimacy with Irving Carry, acknowledging that she had seen her sit in his lap, and occasionally had noticed him put his arm around her, but had "never noticed anything improper."

Montgomery's wife said that the trouble between herself and husband grew out of a disagreement about going to work. He wanted her to work in the Ludlow mills to aid in supporting the family, but she refused. Lack of support was the cause of her desertion from her husband. She confessed that she deceived him with letters, and that she stole twenty dollars from Carry's trunk when she went off, and admitted that on the morning of the murder Carry was in her bed, as he was not feeling well. She acknowledged various intimacies with Carry, but denied anything criminal.

On the way to jail Montgomery muttered, "That damned Carry is the cause of all this," and he also said, "God knows I would n't shoot my little children." Before the shooting he complained of his head feeling bad, slept but little, and "did not eat as a man should who was at work chopping." He spoke frequently of his family, and seemed to think much of his children. At one time he said, "I should rather my children should be in the grave than for them to have another father to rule over them." Sometimes when at work he would drop his head, and seemed to be troubled about something.

Montgomery testified that the day before the fatal shot he could eat nothing, and did not sleep that night. Tuesday morning he remembered dressing the children, and going out for a little, and then returning to the house. He was sitting with his wife, and was talking with her about living with him, and the last he remembered was hearing his wife say, "It's no use talking, Meunie, I shall not live with you again," until he found himself bound in the same room. His wife soon came in and swore at him, saying that he had killed his children, which he denied, as he did not know or would not believe that he had killed his little boy. When he came to himself he had a prickling and numb sensation over his body. He did not know just when, if ever, he had any jealousy of his wife on account of her actions with Carry, but he felt terribly worried at his wife's actions and intimacies with Carry. He bought the pistol with the idea of going West after getting his children.

Dr. Giffilan, jail physician, said that the prisoner had complained of dizziness in the head and want of appetite. When listless the pupils of his eyes would dilate to again contract when he became interested on any subject. Dr. A. W. Thompson, of the Shady Lawn Retreat, said he had visited him at the jail, and found him with a weak voice and a troubled expression about his face. He is apparently a man of weak and varied nature. There is a condition of mind known as transitory mania, though only a few cases are known. Dr. Nims, of the State Hospital, had noticed that Montgomery appeared to be in a listless condition, and that he complained of a pain in his head. Assuming all his testimony to be true we are obliged to decide that he was insane. While the witness had treated over 3500 insane patients, he had never had any personal knowledge of transitory insanity. Dr. Earle, superintendent of the State Asylum, was confident, eliminating all testimony but that of Montgomery, that he was in that condition called insanity at the time of the shooting.

Judge Bassett made a strong plea for Montgomery, in which he said that by the medical testimony he is seen to be like an automaton or a machine without a concurrent mind. Attorney-General Sherman claimed that the act was purely a criminal one, although with some provocation, and protested against the idea that the prisoner was insane one moment and sane the next. The jury rendered a verdict of guilty of murder in the second degree, and the prisoner was sentenced to the State Prison for life. Judge Allen, in dismissing the jury, said that the verdict was in accord with his judgment and that of his associates, and, we may add, with ours.

THE INDEX MEDICUS AGAIN.

FOR the last two years we have called our readers' attention with each recurring close of the year to the propriety and necessity of supporting the *Index Medicus*. Lest any one should plead ignorance, we will say that it is a monthly periodical which gives a list of medical books published during the preceding

month, and also a list of journal articles in all the principal medical journals of the world, classified by subjects. Every man who takes an interest in any particular subject sees at a glance what has been published on that subject, every man who is interested in the welfare of his profession, and believes that welfare is increased by the free interchange of ideas, every man who uses medical libraries, or desires that those who do use them should have an opportunity to use them to the best advantage, should be interested in the existence of the *Index Medicus*.

There is no question as to the value of the publication and the desirability of continuing it, but its use is mostly restricted to the frequenters of libraries, and a single copy in the library, with occasional subscriptions by bibliomaniacs and specialists, supplies the actual wants of the community.

It has been sustained heretofore, in answer to the appeals of its publishers, by contributions from private individuals and societies. Many individuals contributed gladly, or subscribed for extra copies for which they had no possible use, in hopes that its legitimate subscription list would increase sufficiently to insure its continued existence, but the publishers are again obliged to make a statement, which this year is to the effect that there are scarcely six hundred subscribers to whom the *Index* seems to be a necessity, and publisher and editor are agreed that the enterprise must no longer be dependent on voluntary contributions, but must either be abandoned or be placed on the business footing of an equally shared support.

A certain portion of the support of the *Index* has been drawn from various societies, and this suggests the source whence its future support ought to come. Where could our various State societies find an object more worthy their fostering care, or one which would better repay the outlay? A division of the deficit, after a reasonable subscription price by actual subscribers, among the various State societies would unite them in sustaining a work of professional and national pride, and would secure the perpetuation of a work which has become a necessity to the students and writers of the profession.

MEDICAL NOTES.

NEW YORK.

— The forty-first annual meeting of the Society for the Relief of Widows and Orphans of Medical Men was held November 28th at the hall of the Academy of Medicine. Dr. Isaac E. Taylor was reelected president, and Dr. John H. Hinton secretary and treasurer. Seven members of the board of twenty-one managers were also elected to serve three years. The membership now numbers 140, of whom ninety-two are life members, and forty-two annual subscribers. The number of benefactors living is twenty, any one being entitled to this designation who contributes \$150 or more to the funds of the Society. Some of the deceased benefactors have left considerable bequests to the organization, and its total assets on the

19th of September last amounted in value to \$143,447.93. Aid was extended during the past year to thirteen widows and four children of deceased members, and the amount disbursed for this purpose was \$4,251.50. Every widow of a member having an income on property of less than \$800 a year is entitled to assistance from the Society, the annual stipend allowed varying according to the exigencies of the case. Those who are entirely destitute are insured an income of \$400, and destitute children also receive annuities.

— It has been decided that the reports recently made by the Sanitary Inspectors in regard to the condition of the public schools are to be carefully examined by a joint committee from the Board of Health and Board of Education, and needed changes are to be made in those buildings which demand immediate attention. For this purpose the Board of Education has appropriated the sum of \$6000, although it was estimated that the changes needed to correct the insufficient ventilation, bad drainage, and defective plumbing of the schools would cost \$60,000. Still this is better than nothing, and something will, no doubt, be accomplished in the way of improvement. It is said that the President of the Board of Education refused to give the reports of the Sanitary Inspectors to the public because their publication "would depopulate the schools."

— At a meeting of the Medico-Legal Society held December 5th Dr. J. G. Johnson, of Brooklyn, read a paper on Railway Injuries to the Spine, after which the annual election of officers took place. Mr. Clark Bell was elected President; Dr. R. Ogden Doremus, first Vice-President; Mr. Delano C. Calvin, second Vice-President; Mr. Leicester Holme, Secretary; Mr. A. S. Hammersley, Treasurer; Dr. Andrew A. Smith, Curator and Pathologist; and Dr. Charles A. Doremus, Chemist. Dr. William A. Hammond was the opposition candidate for President.

— The investigation of the recent outbreak of diphtheria in the Blind Asylum at Batavia by the State Board of Health showed that the interior sanitary arrangements of the building were very defective, and that the large drain which conducted the sewage to a swamp back of the institution, and which was of concrete, had fallen to pieces, while the earth had caved in and blocked up the passage. The asylum will remain closed until the improvements now in progress under the direction of the Board have been completed.

— There is now living at Penn Yan an individual who for two years has had a bullet imbedded in his brain. In the autumn of 1881 he was shot over the left eye by a drunken companion, and although at first a fatal result was naturally anticipated, in a few months he entirely recovered. The accident is said to have occasioned a complete change in the character of the man, who, previously dissolute, morose, and quarrelsome, has now become a peaceable, sober, and industrious citizen.

— The new hospital for contagious diseases on North Brother Island, East River, is to be supplied

with water from the main land by a pipe 2200 feet in length, which is said to be the longest water-supply pipe ever laid in the bed of any river in this country. By means of it 1,000,000 gallons of Croton water can be furnished to the hospital a day under ordinary pressure.

—The annual meeting and election of the State Charities Aid Association was held December 13th. The Secretary's report embraced the history of the work of forty-four local visiting committees in addition to that of the standing committees and the New York County Visiting Committee with its subdivisions. The subject of the treatment of the insane in poor-houses and in the county asylums was treated at length, and descriptions were given of these institutions in different counties, which exhibited a very unsatisfactory condition of affairs from a moral as well as a hygienic point of view. According to the published report insane patients who might, perhaps, be cured or improved with proper care in State hospitals were found cooped up in close cells like ox stalls, as in Chenango County, or chained like wild animals to strong iron rings in the wall of the yard, as in Genesee County, the lack of suitable attendants making this recourse to restraint necessary. In Broome County the bath-room was found in the coal cellar, and six patients were required to bathe in the same water, which was then saved to wash clothes in the laundry. In Niagara County the insane patients were found shoeless and bare-headed, compelled to sit on the floor, and all, both men and women, under charge of a male pauper. As a general rule the insane in county poor-houses were kept in attics, basements, and out-buildings, which were filthy and squalid. The poor-house buildings in Tioga County in particular were described as old and unsuitable, with a marked lack of bathing conveniences and hospital accommodation. In those of Chenango County were found many distressing cases of suffering and misery, and the institution was described as containing a larger number of mentally and physically diseased inmates than any other in the State. In Fulton County men and women, sick and well, sane and insane, were herded together like cattle, and the sanitary condition of the poor-house buildings in Genesee County was found to be particularly bad. As these various local institutions seemed calculated rather for the encouragement of insanity and misery than for their suppression, the report recommended that poor-house insane wards and county asylums should be abolished, and that all classes of the insane poor should be cared for by the State in cottages of moderate cost erected on the vacant lands of the present six State institutions for the insane. The report also recommended the opening of training-schools for nurses in insane hospitals. Since publication the Secretary of the Association has made the following corrections in the report of the annual meeting of the Society: There are now no insane in the poor-house of Niagara County, all having been removed to State asylums. In Genesee County the statement that lunatics were found chained to the wall is a mistake. In Chenango County there was found a want of proper classification; but the in-

sane are cared for in an asylum adjoining the other buildings.

—In his annual report to Mayor Low, Dr. Raymond, the Health Commissioner of Brooklyn, states that the health of the city has been better during the past year than in any other since 1879. The total number of deaths in the twelve months ending November 30, 1883, was 13,833, or 1180 less than the actual mortality during the calendar year 1882. Estimating the population at 624,118, the death-rate is 22.16 in each thousand inhabitants. In the course of his report Dr. Raymond says: "I am impelled to state my conviction that the efficient operations of the Department of City Works have vastly improved our sewer system, and for some months, at least, have given us pure air to breathe by giving us relatively cleaner streets under the new contract, and have thus indirectly come to the aid of the sanitary authority in its fight against zymotic disease." Attention is then called to the great need for new sewers in the outer wards, which are now being rapidly built up, and the report also recommends that all slaughter-houses shall be removed from the crowded portions of the city.

—The committee of the State Board of Health on Drainage, Sewerage, and Topography have made an investigation of the causes of malaria at Rhinebeck and other places along the Hudson River, and have recommended the construction of suitable culverts through the embankments of the Hudson River and the Hartford and Connecticut Western Railroads, which cut off from the main channel of the river a long narrow cove half a mile north of the station at Rhinebeck. It is the opinion of the Board that the malaria reported at other points along the Hudson is due to similar causes; the railroad embankments preventing the proper flow of the water in and out of the coves thus formed.

—An operation for the removal of a cancer of the breast in a patient at Glenville, New York, recently resulted in erysipelas and tetanus, and the case terminated fatally on the 23d.

—The election at the Society of Medical Jurisprudence and State Medicine was held on the 13th, and resulted as follows: President, Mr. William Barnes; Vice-President, Dr. E. J. Bermingham; Secretary Dr. N. E. Brill; and Treasurer, Dr. E. C. Harwood.

Correspondence.

LETTER FROM ST. PETERSBURG.

ST. PETERSBURG, December 1, 1883.

MR. EDITOR,—In response to your request that I should send you a letter from Europe, in case I should learn of anything interesting to the medical profession in our own country, I take pleasure in forwarding to you the following synopsis of an important practical discovery of a Finnish physician, which will be of great importance to every physician, and the details of which I doubt whether you may receive for some time, because the discovery is only recently given to the medical public.

At a meeting of the Medical Society of Finland of the 10th of November, Dr. Qvist made a communica-

tion concerning a new method for propagating the peculiar bacteria upon whose vitality in vaccine virus the efficacy of its contagion depends. It is not necessary to describe this form of bacteria, since they are well known to microscopists. To propagate these bacteria outside of the animal two conditions are essential:—

(1.) An exposure to common atmospheric air, upon the carbonic acid of which these microzoa live.

(2.) A suitable culture material.

The description of an apparatus which embodies these conditions is not complicated; but unless there is present carbonic acid gas, no development of the vaccine organism can exist. The development of these organisms subsides more readily in every capillary tube which is quite full of vaccine lymph, thus allowing no air space, and especially if these tubes are hermetically sealed; while on the contrary, tubes whose calibre is of a certain size, and which are open, favor their development. Dr. Qvist's experiments proved to him conclusively that these organisms pass through a decided development in open tubes partially filled with vaccine lymph, but that it is not of the same character, in most instances, with that which occurs in the animal body.

A vaccine bacterium is a veritable *aërobium*. In the lymph spaces of the skin there is undoubtedly a sufficient quantity of air containing carbonic acid gas, but this condition can be more readily controlled outside of the body. It is only necessary to have a porous substance, like the meshes of a common sponge, which shall have the property of imbibing a liquid, whose character will form a convenient vehicle for the cultivation of the vaccine bacteria, but a watch glass answers this purpose even better, because the liquid vehicle placed in it may have its upper surface more thoroughly exposed to the active influence of common air.

Dr. Qvist has used for this culture fluid egg albumen, which is better than the more solid forms of albumen. Egg albumen has properties which are in many respects similar to the serum of the blood. Yet it is not improbable that the mineral portions of egg albumen combined with ammonia and some organic oxide may serve equally well for a propagating medium, though this remains for further investigation. He prefers to use glycerine with egg albumen, not because it forms an important ingredient of the culture fluid, but because without its presence the albumen is liable to a partial desiccation which prevents the cultivation or propagation. Vaccine bacteria require during their development a larger proportion of glycerine than other micro-organisms, especially those of the fungus character, such as may grow upon old leather, for the following reasons: mould fungi may possibly destroy or prevent the growth of vaccine bacteria; hence as the former require less glycerine, and are really destroyed by too much of it, the latter may exist more favorably in a vehicle containing rather more glycerine than is ordinarily used in the cultivation of these mould fungi. Therefore this condition of their vitality is an important matter. Mould fungi also live by preference in a liquid vehicle which has an acid reaction; while, per contra, vaccine bacteria like their congeners exist by preference in a vehicle of an alkaline reaction.

The following list of culture fluids used by Dr. Qvist does not presuppose that there are not others possessed of equal value for the propagation of vaccine bacteria, and he recommends as those which experience has

shown him to fulfill all necessary conditions the first four named:—

No. 1.	Bovine blood serum	1 part.
	Glycerine	1 part.
	Distilled water	1 part.
	Calcic carbonate	1-800 part.
No. 2.	Bovine blood serum	2 parts.
	Glycerine	1 part.
	Distilled water	2 parts.
	Calcic carbonate	1-400 part.
No. 3.	Egg albumen	1 part.
	Glycerine	1 part.
	Decoct. althææ radicis	1 part.
	Calcic carbonate	1-150 part.
No. 4.	Egg albumen	1 part.
	Mucilag. gum acaciæ	6 parts.
	Calcic carbonate	1-60 part.
No. 5.	Tartrate of ammonia	1 part.
	Phosphate of calcium	1-10 part.
	Carbonate of calcium	1-5 part.
	Sulphate of magnesium	1-50 part.
	Chloride of calcium (vel calcium chlorum)	1-100 part.
	Distilled water	100 parts.
	Glycerine	30 parts.

The following means should be used to destroy the organisms which are peculiar to the culture fluid itself. It should be subjected to a constant temperature of 60° C. for one and a half hours continuously on three successive days. Dr. Qvist has proved this means of sterilizing the culture fluid by frequent microscopical examinations of it after the above process, and has not found the development of any organisms even in a specimen kept for three months. All the other ingredients used in the culture fluid have either been subjected to a similar sterilizing process or have been used immediately after being warmed or heated.

As he found that the usual summer heat or that of a warmed house in winter, at 19° C. to 20° C., has favored the propagation of these bacteria, he has not experimented with any other variations of temperature.

As seed for transplantation of vaccine bacteria he has used vaccine lymph just ripe or a little old, and which has been found by experimentation to be capable of producing a true vaccine pustule. Then a piece of dry sponge, completely sterilized by the above process, is allowed to imbibe a little of this selected vaccine lymph, and is immediately transferred in a culture fluid placed in a watch glass.

But a more convenient and safe method is accomplished by taking a piece of the epidermis from a true vaccine pustule, but taking pains not to allow any of the blood serum to be attached to it, because the epidermis itself is sufficiently saturated with pure vaccine lymph. To do this successfully a small portion of the epidermis should be taken from a vaccine vesicle on the eighth to the tenth day according to the character of its development, by gently lifting and separating it from the whole vesicle, then cleaning it by washing, and then after one or two days' careful drying it should be immediately placed in the culture fluid. This solid mass of seed, if not injured by outward circumstances, has always proved efficacious.

The watch glass should be three or four centimetres in diameter, and is the most convenient vessel for use when it is desired to propagate rapidly the vaccine virus in a dilute form. The watch glass should be placed on a table or shelf and exposed to moist air and covered by a cleaned tumbler.

When it is desired to produce a concentrated form

of virus a test tube is preferable, and it should be corked with a paraffine coated cork, taking care to sterilize the paraffine, and to allow a small air-hole on the side of the cork.

If the surface of the culture fluid be examined even in a day or two, it will become turbid, and in the course of a week or ten days scales will form over its upper surface in a series of floating islets, and a fine powder will fall down to the bottom of the glass. This powder, which is also attached to the scales, contains the bacteria. At first the culture fluid is turbid, but gradually it assumes a yellow or straw color, and these physical appearances are increased by obliquely reflected light.

Vaccine lymph thus artificially prepared can be preserved in capillary glass tubes and used as required.

Dr. Qvist then cited several cases in which he proved by inoculation that his artificially prepared lymph produced pure vaccine vesicles. I will not weary your readers with the details, but trust that his experiments will be verified by some of our countrymen.

Very truly yours, ROBERT AMORY.

"A CASE OF DELAYED PUTREFACTION."

NEW BEDFORD, December 1, 1883.

MR. EDITOR,—In an article entitled *A Case of Delayed Putrefaction*, by W. H. Taylor, M. D., Medical Examiner, published in the *JOURNAL* for November 15, 1883, the following statement is made: "Her attendants were of the homœopathic persuasion, and I am unable to obtain a coherent history from them. The consulting physician made some vague remarks about 'trouble with the pneumogastric,' from which I inferred that the respiration showed some abnormal qualities. He was, moreover, strongly of the opinion that the deceased had been poisoned, and named gelsemium as the agent employed. She had no marked dyspnoea, no marked pulse change, no vomiting, pain, or diarrhoea, and passed a good quantity of urine in which no albumen had been discovered. The information derived from the attendants was sufficiently vague and inconclusive."

As the consulting physician here alluded to, I "rise to explain." So far as I am concerned, the only reason for the failure of the examiner to obtain information from me was that he did not ask for it. It was only after the so-called autopsy was made, and after the viscera had been sent to the chemist with its accompanying misinformation, that I learned that any examination had been thought of. The "vague" remarks that he attributes to me were in response to a "vague" question put to me at a chance interview, and appear, by his statement, to have been almost wholly misunderstood.

For example, I was *not* "strongly of the opinion that the deceased had been poisoned;" nor was my mention of gelsemium more than a suggestion that, instead of skull-cap, she had possibly got gelsemium by mistake.

The remaining symptoms given by Dr. Taylor, and for which I am in no wise responsible, are at fault in nearly every particular. There *was* vomiting, dyspnoea, pain, and diarrhoea.

Considering the importance of the case to the friends of the dead and to the welfare of the living, upon whom suspicion rested, I submit that the imperfect manner

in which this examination was conducted, the neglect in obtaining proper information of the ante-mortem condition,—an autopsy by the "sole light" of a "feeble petroleum lantern,"—with no "conveniences for testing the valves of the heart," etc., go far to show the unfitness of Dr. Taylor for the extremely responsible position he occupies.

HENRY B. CLARKE, M. D.

"EPIDEMIC APPROPRIATION," MARINE HOSPITAL SERVICE.

NEW YORK, December 7, 1883.

MR. EDITOR,—In the *JOURNAL* for December 6th I notice, in your review of the report of the United States Marine Hospital Service, the following statement: "The entire expenses on account of the epidemic appropriation for the two years, up to June 30, 1883, was \$54,678.10." While this statement is strictly true, it gives the reader a false impression. The fiscal year ends on the 30th of June. At that date, therefore, the account of 1882 is rendered, and the appropriation ceases to apply. On the 1st of July the appropriation of 1883 becomes available, while that which remains unexpended of the appropriation of 1882 is turned into the Treasury. The truth is that of the \$100,000 "epidemic appropriation" for the fiscal year ending June 30, 1883, the Marine Hospital Service expended \$54,678.10. How much it has expended of the \$100,000 "epidemic appropriation" for the fiscal year ending June 30, 1884, we shall not know until a year hence.

Yours, N****.

Miscellany.

OBITUARY. CALVIN ELLIS, M. D.

DR. CALVIN ELLIS, who died at his residence in Boston last Friday, December 14th, was born in Boston, at the corner of McLean and Chambers Streets, in 1826, being, therefore, at the time of his death fifty-seven years old. He was the son of Luther Ellis, a prominent iron merchant. Dr. Ellis received his early education in the Chauncy Hall school, entered Harvard College in 1842, and graduated in 1846. After leaving college he entered the medical school, from which he took his diploma in 1849, serving then a year in the Massachusetts General Hospital as house physician, and spending two years abroad in study before beginning the practice of medicine in this city. He was appointed Professor of Clinical Medicine in the Harvard Medical School and visiting physician at the General Hospital in 1864, succeeding Dr. H. I. Bowditch in both offices. He was a member of the Massachusetts Medical Society since 1850, of a number of medical societies, and was a Fellow of the American Academy of Arts and Sciences. He contributed several valuable papers to the pages of this journal, and at the time of his death was engaged upon a book upon Symptomatology, which he leaves unfinished.

The origin of the malady, duodenal ulcer, which brought Dr. Ellis's active and useful career to a premature close, probably dates back at least ten years. In 1874, when returning from one of several visits to Vienna, he experienced a good deal of abdominal dis-

tress, attributed at the time to the disturbance of the sea voyage. For the last three or four years little doubt has been entertained of the diagnosis of ulcer of the duodenum. They have been years of much suffering, well borne, in which the discharge of professional duties as a teacher and practitioner has been greatly interfered with, and latterly rendered impossible.

The end came in the usual way, by perforation of the intestine and general peritonitis.

This is hardly the time or place to speak of Dr. Ellis's merits as a teacher and practitioner of medicine. Justice will undoubtedly be done to them later. His whole heart was in his work, and he was in all he undertook a most painstaking and conscientious laborer, never sparing himself. The interest he took in the discharge of his political duties as a citizen should be an example to younger men, and one of the last marks of interest in our profession was the excellent card catalogue of the Boston Medical Library Association, which is due entirely to his thoughtful generosity. He was never married, and leaves a sister as the surviving member of the immediate family.

OBITUARY. FRIEND DRAKE LORD, M. D.

FRIEND DRAKE LORD, M. D., died on the 8th inst., at Newton Lower Falls, Mass.

Dr. Lord was born in Limington, Me., March 3, 1822, and was graduated in medicine at Bowdoin, Me., 1847. Immediately after, he visited New York and Philadelphia to perfect himself in his profession by study and observation in the hospitals of those cities. After several months he returned to his native State to engage in practice, but soon after came to this State, residing for a short time in West Dedham. He then went to Sterling, where he practiced for eight years. Fourteen years ago he removed to Newton Lower Falls, where he has since been engaged in the arduous duties of his profession. A few years ago he lost, by a sudden and painful illness, his only son, a young man of superior abilities, of unusual promise, and at the time an undergraduate at Harvard University. He began to fail in health soon after, but continued to perform his labors at the bedside till three weeks ago, when he was violently thrown against a tree, which aggravated the diseases already existing, and caused his death on the 8th inst.

As a man he was upright, retiring in his disposition, but genial. As a physician he was painstaking, careful, and sympathetic, winning the confidence and love of the several communities in which he resided. An unusually large circle of professional friends and patients extends its sympathy to his widow and daughter in their bereavement. I. H. HAZELTON, M. D.

REPORTED MORTALITY FOR THE WEEK ENDING DECEMBER 8, 1883.

Cities.	Population by Census of 1880.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from				
				The Principal Infectious Diseases.	Consumption.	Typhoid Fever.	Diphtheria and Croup.	Scarlet Fever.

Deaths reported 2651 : under five years of age, 888 : principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 484, consumption 396, lung diseases 301, diphtheria and croup 196, scarlet fever 62, typhoid fever 60, diarrhoeal diseases 46, measles 35, whooping-cough 25, malarial fevers 22, cerebro-spinal meningitis 18, erysipelas 12, small-pox four, puerperal fever four. From *diarrhoeal diseases*, New Orleans 13, New York nine, Boston six, Brooklyn and Cincinnati four each, Baltimore three, Buffalo two. St. Louis, District of Columbia, Milwaukee, New Haven, and Lowell one each. From *measles*, District of Columbia 10, New York six, Brooklyn five, Baltimore four, Philadelphia and Boston three each, Chicago two, Pittsburg and Providence one each. From *whooping-cough*, Baltimore seven, Brooklyn five, District of Columbia four, New York and Boston three each, Philadelphia, New Orleans, and Buffalo one each. From *malarial fevers*, St. Louis and New Orleans six each, Brooklyn four, New York three, Chicago two. From *cerebro-spinal meningitis*, New York six, Philadelphia, Cincinnati, Somerville, and St. Louis two each, Chicago, Baltimore, Providence, and Fall River one each. From *erysipelas*, Brooklyn five, New York two, Philadelphia, Boston, Cincinnati, Buffalo, and Springfield one each. From *small-pox*, New Orleans three, Philadelphia one. From *puerperal fever*, St. Louis two, New York and Boston one each.

Five cases of small-pox were reported in St. Louis ; scarlet fever 65, diphtheria 48, and typhoid fever 26 in Boston ; scarlet fever 18, and diphtheria 40 in Milwaukee.

In the 67 cities and towns of Massachusetts, with an esti-

mated population of 1,131,434 (estimated population of the State 1,922,530), the total death-rate for the week was 19.52 against 16.56 and 18.59 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending November 24th, the death-rate was 22.7. Deaths reported 3748 : acute diseases of the respiratory organs (London) 445, scarlet fever 118, measles 96, fever 70, whooping-cough 63, diarrhoea 53, diphtheria 34, small-pox (Sunderland four, London, Wolverhampton, and Liverpool one each) seven. The death-rates ranged from 15.2 in Derby to 31.7 in Manchester ; Birmingham 20.4 ; Leicester 20.5 ; London 22 ; Nottingham 22.2 ; Birkenhead 23.5, Liverpool 24.1 ; Leeds 24.8 ; Sheffield 25.3. In Edinburgh 25.4 ; Glasgow 29.2 ; Dublin 33.

For the week ending November 17th, in the Swiss towns, there were 23 deaths from consumption, lung diseases 19, diarrhoeal diseases six, typhoid fever five, whooping-cough four, diphtheria and croup three, measles one. The death-rates were, at Geneva 13.3 ; Zurich 20 ; Basle 9.5 ; Berne 19.2.

For the week ending November 24th, in the Swiss towns, there were 26 deaths from consumption, lung diseases 14, diarrhoeal diseases 10, whooping-cough seven, diphtheria and croup six, puerperal fever two, measles one, scarlet fever one, erysipelas one, typhoid fever one. The death-rates were, at Geneva 12.3 ; Zurich 16 ; Basle 10.3 ; Berne 18.1.

The meteorological record for the week ending December 8th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps : —

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM DECEMBER 7, 1883, TO DECEMBER 14, 1883.

SHUFFELDT, ROBERT W., captain and assistant surgeon. Now on sick leave, relieved from duty in the Department of the East, and assigned to temporary duty in the office of the Surgeon General of the Army. Paragraph 12, S. O. 284, A. G. O., December 12, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEKS ENDING DECEMBER 8, 1883, AND DECEMBER 15, 1883.

KINDLEBERGER, D., medical inspector. Ordered to the U. S. S. Hartford, Pacific Station, per steamer of the 10th inst.

GHON, A. L., medical director. Detached from duty as member of Board of Inspection and Survey on the 15th inst., and placed on waiting orders.

PECK, GEORGE, medical director. Ordered to report on the 15th inst. as member of the Board of Inspection and Survey.

DEARBORNE, F. M., surgeon. Placed on the retired list from December 10th.

HEFFINGER, A. C., passed assistant surgeon. In addition to his duties at the Navy Yard, ordered to attend officers at Portsmouth, N. H.

NORFOLK DISTRICT MEDICAL SOCIETY. — A meeting for Scientific Improvement will be held at the Medical Library, 19 Boylston Place, Boston, on the evening of Thursday, December 20, 1883, at seven P. M. Communications : The Sanitary Condition of Country Towns, J. A. Gordon, M. D. Report of a Case of Gangrene of Lung with Fetid Empyema, H. W. Broughton, M. D. Diphtheria, F. W. Vogel, M. D. ———, W. C. B. Fifield, M. D.

G. D. TOWNSEND, M. D., Secretary.

BOOKS AND PAMPHLETS RECEIVED. — The Dissector's Manual. By W. Bruce-Clarke, M. A., M. B., F. R. C. S., etc., and Charles Barrett Lockwood, F. R. C. S., etc. Illustrated with forty-nine engravings. Trephining the Spine. A Case? — Death! By Wm. H. Myers, M. D., Ft. Wayne, Ind.

The Late Dr. George M. Beard. A sketch by A. D. Rockwell, M. D. Read before the American Academy of Medicine, New York. 1883.

Original Articles.

SPINAL IRRITATION; PROBABLE CEREBRAL ORIGIN OF THE SYMPTOMS, SOMETIMES CLASSED UNDER THIS HEAD.

BY G. L. WALTON, M. D.

THE rôle played by the term spinal irritation has of late been greatly limited. Many cases formerly so classed have found their place under hysteria, and many more under hypochondria, both presumably diseases whose symptoms result from functional disturbance of the brain rather than of the spinal cord. The effort has been made, and with considerable success, to collect the remainder of these "nervous" cases under the term neurasthenia, while the subdivision adopted by some authors into cerebrasthenia and myelasthenia, denotes that some of the symptoms are supposed to be of cerebral, others of spinal origin.

The object of this paper is not to discuss the classification of these diseases, but to consider the relative importance of the brain and the spinal cord in the causation of those symptoms concerned, which are by many authors still attributed to "spinal irritation." It is upon the accurate analysis of these symptoms that the final classification must rest, and until this goal is reached, all efforts to arrive at exact diagnoses, and to distinguish the real from the feigned, will be but groping in the dark. This fact is not recognized by those who depreciate the importance of looking for the seat of the morbid process, and who, inverting the scientific order, propose to separate the real from the feigned among the symptoms before studying the causation and character of those symptoms.

It is the tendency of modern neurological research to transfer to the brain much of the attention hitherto given the spinal cord, but the preservation of the term spinal irritation in prominent text-books shows that there exists a set of symptoms which the medical as well as the non-medical world still ascribes to a disordered "spine." The disease called railway spine includes practically the same symptoms, if we exclude the cases in which real lesion, as hæmorrhage, exists in the cord, and this name expresses the idea that a jar to the spinal column has caused the same symptoms that sometimes follow overwork, mental strain, and the various causes of so-called neurasthenia.

Erb represents the views expressed in many text-books, when he includes under spinal irritation such symptoms as vertigo and headache, sleeplessness, inability to confine the attention, and mental irritability, and states that when the disturbance is high up in the cord these symptoms are more prominent than when it is low down. He assumes that these manifestly cerebral symptoms are dependent upon spinal disorder, although he recognizes the fact that the spinal disorder itself rests upon a mere hypothesis, and states that in the absence of pathological data the theories of spinal hyperæmia, anæmia, etc., must be regarded as merely conjectural.

The line of argument in this paper is intended to show, in the first place, that the presumptions on anatomical and physiological grounds are all in favor of the brain, rather than the cord, as the centre not only of these but also of the more general symptoms ascribed to spinal irritation; and in the second place, that in point of fact all the symptoms can be more satisfactorily

explained by supposing functional disturbance in the cerebral than in the spinal centres, while many of the symptoms can be explained only in this way. If these conclusions be established, we must look to the brain as the chief centre of the difficulty, and the cord as playing, if any, a subordinate part.

It should be premised that we cannot hope as yet to arrive at the exact pathology of the disorder in the cerebral centres. The distinctive characteristic of these cases is the absence of demonstrable lesion. Whether these functional affections of the nerve cells are due in the various cases to malnutrition (as in lithæmia), to vaso-motor irregularities, to molecular disturbance (as in concussion), or possibly to irritation through the sympathetic nervous system from abdominal or other organs, are subjects at present under discussion. It is highly improbable that any one pathology will be found applicable to all cases; perhaps all of the above causes play their part separately or in combination, so that each case must be analyzed by itself.

These symptoms may be practically considered peculiar to the human race, although they perhaps obtain to a certain degree among animals below us in the scale of development. This fact leads us to inquire what part of the nervous system is most fully developed in the higher animals, and what part is peculiar to the human race?

The answer is easy. The development of the cerebral hemispheres is not only the most distinctive feature of the higher animals, but it is the one peculiarity which gives man his supremacy among them.

On the surface of these hemispheres lie the nerve cells which constitute the final centres of sensation and motion, and which are generally acknowledged to be the seat of the mental processes. It is these delicate centres which are probably the chief sufferers in the nervous cases under consideration. It is not claimed that the spinal cord of man is on exactly the same plane of development with that of the lower vertebrates. Allowing, however, a considerable superiority in the spinal centres in man over, for example, those of the dog or monkey, we must still consider the difference trifling as compared with the difference between the brain of such an animal and that of man.

These facts do not in themselves show that all functional nervous symptoms peculiar to man come from the brain; they should, however, be taken into consideration in looking for the seat of symptoms which admit of explanation by either cerebral or spinal disturbance, especially when such symptoms are accompanied, as they almost invariably are, by those of evidently cerebral origin. As an example, a certain case presents among other symptoms mental irritability and local anæsthesia; the latter can be explained as arising either from the brain or the spinal cord; the former cannot be explained without the brain. The presumption is therefore in favor of the brain as the seat of both symptoms, whereas the old classification would attribute both to the spinal cord.

The ætiology of these cases is instructive. Lively emotions, mental distress, unrequited love, are mentioned by many authors as exciting causes of spinal irritation. Now the supposition that such stimuli as these affect the spinal cord, excepting through the brain, is absurd; but we have become so used to associating these symptoms with the spine as to have overlooked or forgotten the fact that the brain is the organ

primarily affected. It requires no stretch of the imagination to assume that the highly organized and exquisitely sensitive cerebral centres whose function it is to receive and interpret the stimuli which give rise to the mental processes may be disturbed in the exercise of their functions when such stimuli become excessive. In fact, the delicacy of organization which the cerebral nerve cells *must* have to perform their complicated functions furnishes alone a strong presumption for attributing to them the irritability and depressibility hitherto ascribed to the spinal cord, an organ containing only the lower reflex centres, which preside over functions possessed by man in common with animals far below him in the scale of development.

Trauma, in the form of falls, blows, and collisions, figures largely in the ætiology of these cases, and the nervous symptoms following a jar to the whole body have been for some time attributed to disorder in the cord, under the name of railway spine. It seems, probable, however, that "railway brain" would be a more appropriate term, first, because these delicate cerebral nerve cells must be more susceptible to a jar than the lower spinal centres; and secondly, because the spinal cord, an organ light in weight, hangs suspended in a large amount of fluid, loose areolar tissue, and a plexus of veins, while the comparatively heavy brain lies almost in contact with its bony case, rendering its mechanical liability to a shock much the greater of the two.

If the spinal cord were to suffer so severely in man from a moderate jar, we should expect a cat, whose spinal cord is approximately delicate as ours, to show some slight symptoms on falling from a height. Her immunity is probably due to the comparatively undeveloped state of her brain. In point of fact a patient suffering from so-called railway spine always exhibits mental irritability, emotional tendency, and other symptoms of evident cerebral origin. Recent investigation¹ has also shown that unilateral loss of sensation, including the head and special senses, is not unfrequently found among the symptoms, which absolutely establishes, at least in these cases, a disturbance of cerebral function.

There seems to be at present a strong movement in favor of attributing neurasthenical symptoms in many cases to lithæmia or suppressed gout. This by no means interferes with placing the seat of the symptoms in the brain, for the cerebral nerve cells may be safely considered at least *equally* liable with those of the spinal cord, or with any organ of the body, to malnutrition from disordered blood supply.

One other cause of "spinal irritation" should be considered before passing to the symptomatology. This is excessive sexual excitement. The fact that the reflex centres for erection and ejaculation are seated in the spinal cord should not lead us to identify with that region all irregularities connected with the sexual functions. We must not forget that these spinal centres are in connection with, and to a certain degree subservient to, higher cerebral centres. This is evidenced

by the fact that erection itself, while capable of being brought about in a purely reflex way, may also be produced by a thought. On the other hand it may be inhibited by a fear, as, for example, the very fear of not being able to perform the act of coitus. This subject will be alluded to again, and is mentioned here merely to remind the reader that the nervous symptoms which sometimes follow excessive sexual excitement may as well be attributed to the shock which these higher centres have received as to injury of the spinal centres connected with the mechanical portion of the sexual act.

All the symptoms of so-called spinal irritation will be found, on careful analysis, to admit of satisfactory explanation by disordered function of the cortical cerebral nerve cells, to whose sensitiveness we have alluded, and which have been stated to constitute the final centres of sensation and motion. Confining ourselves to those symptoms which seem to have been hitherto most plausibly connected with the spinal cord, we shall consider in detail only a few of the more prominent, the rest falling readily into line when analyzed in a similar manner. Such symptoms as hopelessness, morbid fears, sleeplessness, mental irritability, and inability to confine the attention, may be left out of consideration as being obviously of cerebral rather than spinal origin. The disturbances of special sense, as asthenopia, amblyopia, and nervous deafness, may be passed by for the same reason.

Besides symptoms of these two classes no less than forty others are mentioned by Beard in his work on neurasthenia, among which are included, perhaps, nearly all which have ever been attributed to spinal irritation. Among them we find pains in the back, sensitiveness of the spine to pressure, weakness in the back, tenderness of the scalp, heaviness of the loins and limbs, sensitiveness to the weather, special idiosyncrasies in regard to food, medicines, and external irritants, anæsthesia and hyperæsthesia in various parts of the body, and impotence.

The fact that these patients complain of *pains in the back, sensitiveness of the spine, and weakness in the back*, perhaps explains in great measure the association in our minds of all the other symptoms with the spinal cord. These symptoms are, however, among the easiest to dispose of. As far as we know there are no nerve cells in the cord capable of feeling. The cord can, it is true, answer stimuli by reflex action, as is seen in the decapitated frog who withdraws his foot from the acid. We do not, however, imagine that he *feels* the irritation of the acid in the ordinary acceptation of the expression to feel. Certainly no physiologist fancies that a decapitated man feels external stimuli. On the contrary the centres of sensation lie in the brain, and when we feel a pain in the back it is our cerebral centres which feel the pain. This means that a disagreeable sensation is produced by, for example, pressure on the nerve fibres distributed to the regions of the back, whether the external regions, as the skin, or the deeper-seated parts, as the membranes of the cord. That is to say the neuralgic pains in the back belong to the same category as those in the arms, legs, or face, and have nothing to do with the spinal cord itself excepting that the sensory nerves travel through the cord to reach the brain. If, then, the pains are caused by the irritability of any nerve centres it is by the irritability of cerebral, not spinal, centres. These pains, like those of hypochondria, with

¹ "Recent Investigations into the Pathology of so-called Concussion of the Spine, with Cases illustrating the Importance of seeking for Evidences of Typical Hysteria in the Chronic as well as the Acute Stages of the Disease." J. J. Putnam, M. D., Boston Medical and Surgical Journal, September 6, 1883. See, also, the following articles by the writer: "Possible Cerebral Origin of Symptoms usually Classed under Railway Spine," Boston Medical and Surgical Journal, October 11, 1883; and "Case of Typical Hysterical Hemianæsthesia in a Man, following Injury," Archives of Medicine, New York, July, 1883.

which they are really coincident, probably mean that the cerebral centres are so sensitive that the normal pressure of part upon part in the body becomes painful, just as the auditory centres become sometimes so sensitive that the ticking of a clock causes distress, while in the normal condition it would hardly be noticed.

The term spinal irritation, therefore, used as it undoubtedly is to express the idea that irritability of the spinal nerve cells furnishes the basis for these symptoms, is certainly misleading.

Sensitiveness of the spine to pressure has probably no more to do with the spinal cord itself than sensitiveness at the supra-orbital notch in frontal neuralgia. The tender spots over the spine represent the course of the sensitive nerves over the spinal cord, not the nerve cells in the spinal cord. *Sensitiveness of the scalp*, one of the most common symptoms, falls into a similar category excepting that when it occupies parts of the scalp supplied with sensation by nerves which do not even pass through the cord on their way from the brain to the periphery, the absurdity of considering the spine the seat of disorder becomes the greater.

The feeling of *weakness in the back* means probably that the muscles of the back are wearied in holding up the vertebral column, just as any other muscles may tire of performing their functions, and we have no reason for seating the feeling of weariness or weakness in the spinal centres, but must refer these sensations directly to the brain, the seat of all feeling. The sense of *heaviness in the loins and limbs* must be classed with the feeling of weakness in the back, requiring therefore no further discussion.

Special idiosyncrasies in regard to weather, food, medicines, and external irritants may be all classed together as common to hysterical, hypochondriacal, and so-called neurasthenical patients, as well as those suffering from "railway spine." Such patients report the most severe symptoms following directly upon the application of cold water or electricity, and upon the exhibition of drugs in absurdly minimal doses. In such a patient a wet pack may cause weakness and trembling for days, and an apparently alarming prostration may follow a brief exposure to the heat of the sun. Such symptoms are apt to vary greatly in severity according to the solicitude of the family and the interest of the medical attendant, and while they are by no means to be passed by with the mere word "imaginary," they are so obviously to be explained by perversion of cerebral function as to require no discussion in this paper.

Anæsthesia and hyperæsthesia, however limited in extent, may be of cerebral as well as spinal or peripheral origin, and when these disturbances occupy the whole of one side of the body, including the head, they can only be explained as arising from the brain. Now a number of these cases have been found to suffer from unilateral loss of sensation, not only involving the integument of the head, but also the special senses. This fact alone leaves the presumption in favor of the brain as the seat of all the disturbances of sensation.

The last symptom on the list is *impotence*. The lower and higher centres presiding over the sexual act have been already alluded to. Attention has been called to the fact that the spinal centres for erection and ejaculation are under the influence of the higher cerebral centres; that the reflex may be started by a thought and may be inhibited by a fear. While confidence is a necessary factor in the consummation of the sexual act, depression, anxiety, or even the diversion

of the mind into other channels may prevent it. Interesting cases have been recorded in which the thoughts of business or of a mathematical problem have persistently prevented the consummation of the marital relations in persons otherwise healthy. These facts illustrate the close relation between the mind and the sexual activity; and if a mere emotion, or the diversion of the thoughts to other subjects, can render a comparatively healthy man temporarily impotent, it must be allowed that persistent functional derangement of the cerebral centres may cause lasting impotence.

The arguments in this paper tend to show that, —

(1.) The presumptions on anatomical and physiological grounds are all in favor of the brain rather than the cord, as the seat of the functional nervous disturbances, attributed by some authors to spinal irritation.

(2.) In point of fact the symptoms involved are more satisfactorily explained on the ground of cerebral than of spinal disorder.

No exhaustive discussion of the subject has been attempted, but it is hoped that this brief sketch of the main points at issue will serve to throw doubt upon the appropriateness of the term spinal irritation, at least with its present signification. It is believed that the views here advanced are so far in accordance with the tendency of recent neurological research as to meet with general recognition. In this case the mental symptoms in neurasthænia and allied diseases will surely be considered by no one as dependent upon spinal trouble, but will be looked on as indicative of the disturbance of cerebral function which gives rise to these and all the other symptoms. The accurate localization of the symptoms being once determined, the field is cleared for the study of the pathological changes giving rise to the disturbance.

LARGE VESICAL CALCULUS IN AN INSANE PATIENT. REMOVAL THROUGH VAGINA. DEATH ON SIXTH DAY. AUTOPSY.

BY C. P. BANCROFT, M. D.,
Superintendent New Hampshire Insane Asylum.

PATIENT thirty-eight years of age. Has been insane for over two years. The form of her insanity, chronic mania, with hallucinations of hearing and smell. During the entire period of her insanity patient has been much excited, at times incoherent, and generally very irritable and capricious. For a long time she insisted that there were noises in her ears, and expressed it as her opinion that there was some animal lodged within the external ear. She made many attempts to reach this imaginary animal by inserting rags, hair-pins, sticks, and other foreign bodies. Finally she insisted that there was a skunk in her nose, and that the odor was very perceptible to her. She introduced a piece of stout wire, seven inches long and bent on itself, into the right nostril, and passed it back into the posterior nares. One point appeared at the nostril, and the other curved up and inserted itself between the nasal bones at their junction with the upper lateral cartilages. The blunt end, which resembled the closed end of a hair-pin, was back in the posterior nares. This wire I was obliged to cut an inch within the nasal cavity, and, by making an incision between the two nasal bones, remove one part through the bridge and the other part through the nostril. After this episode

the patient began to entertain the idea that something was lodged within the bladder. Finally, while alone, and entirely unbeknown to others, she passed a hair-pin into the urethra. This was caught up by muscular contraction and carried beyond her reach. Soon vesical irritation declared itself, and after a little while the patient voided a hair-pin pretty completely encrusted with urinary salts. Notwithstanding that her suffering must have been intense, she made no complaint, and consequently nothing was known of her trouble until she presented the hair-pin to the medical interne, Mr. J. P. Dana. But about this same time, April 1, 1883, the patient, unbeknown to others, inserted a second hair-pin. The passage of the first, together with a temporary amelioration of symptoms, led us to think that the trouble was over. From this time until October the patient made no complaint, but studiously kept by herself. Having an insane dislike to myself and to the assistant physician, Dr. Benner, she would allow neither of us to approach her. It is certainly remarkable that during this long period of most intense suffering she never made any complaint, her insane delusions in regard to persons and things enabling her to endure the most exquisite pain without making the slightest mention of it. Finally her suffering became so great that she could not disguise the fact in her physical appearance. She began to remain in bed, and appeared depressed and very unlike her maniacal self. During the last of October I was able to get her confidence sufficiently to induce her to make a true statement of her real condition. She then told me that she suffered the most intense pain in passing water; that she could only void it when on her hands and knees and by pressing over the pubes. I questioned her more closely, and she admitted that she inserted *two* hair-pins instead of one about the first of April. A period of seven months had therefore elapsed from the date of the insertion of the hair-pin and her first mention of it.

On October 28th I passed a silver catheter, and detected a hard substance at the neck of the bladder. The finger in the vagina disclosed a hard projection at the same point.

On November 2d patient was etherized. Assisted by Drs. Walker, Benner, and Pearson, I gradually dilated the urethra so that the forefinger could be admitted. The tip of the forefinger came directly upon the calculus at the neck of the bladder, and disclosed the fact that the stone bulged rapidly from the end first felt, and that it was one of very large size. As extraction through the urethra was out of the question I introduced a grooved director, and with patient in Sims's position made an incision an inch and one eighth long through the vesico-vaginal septum. Through this opening the stone was removed. It was as large as a medium-sized hen's egg, weighed 950 grammes, and presented the two points of a hair-pin projecting toward the neck of the bladder, the blunt end appearing at the upper part of the stone toward the fundus. The base where the stone rested was rough and gritty from particles of phosphatic concretion. After thorough cleansing the incision was closed with four silver sutures and patient returned to bed. After the operation she rallied very slowly; there was some vomiting; pulse was very weak and thready. Rectal and subcutaneous injections of brandy revived her to some extent.

November 6th. The record says: "The history of

the past few days has been one of weakness and uncertainty. Her stomach has refused all nourishment, and the suspicion arises that the vomiting may be due to imperfect action of the kidneys. Yesterday and the day before injections per rectum were instituted." The bladder was washed out, but the water returned almost as soon as injected. Incontinence is a marked feature, the urine dribbling constantly from the urethra. Menstruation commenced to-day. Patient troubled with hiccoughs.

November 8th. Night before last watery discharges from bowels began, and the following forenoon the vomiting almost entirely ceased. The weakness continues, however. At no time since the operation has there been fever or a pulse faster than 96. But the pulse has been, though slow, extremely weak. Patient has been perfectly clear in mind up to last evening. This has been a very characteristic feature in the case. Whenever the patient has been severely prostrated physically she has invariably presented symptoms of mental improvement. During the entire period since operation she has discussed her case as intelligently as a sane person could have done. So frequently does this occur in the insane who become physically prostrated that one is often reminded of a metastasis, and led to conjecture whether a morbid element circulating in the cerebral centres has not actually removed itself to some other more vulnerable part. However this may be, last evening patient began to appear drowsy. This sleepiness has continued to-day. She would be aroused sufficiently to take nourishment, and immediately go to sleep. Pulse has continued about 96, with no fever. About five p. m. she suddenly exclaimed to the nurse that she suffered extreme pain in the right iliac and hypogastric region, and asked her to turn her over. She also said that she was dying, and wished the nurse to send for a physician. The nurse helped turn her over, but she almost instantly collapsed. Within five minutes I was present, but she was dying as I entered the room.

Autopsy nineteen hours after death. Rigor mortis well marked. Bladder, uterus, ovaries, and upper wall of vagina removed entire. The anterior wall of bladder was so firmly adherent to the anterior wall of abdominal cavity that it could only be separated with some force and by careful dissection. The entire mucous surface of the bladder was very dark, congested, and thickened, and bore evidences of long-continued suppuration. The walls of the bladder presented two large cysts: one in the right wall, about midway between fundus and neck, evidently developed about the point where right ureter entered the bladder; the other cyst was at the very fundus. The antero-posterior cyst was quite large, and was firmly adherent to the anterior walls of abdominal cavity. The interior of this cyst was filled with fibrous bands, phosphatic accumulations, and fetid pus. On the external wall of this cyst were two points of ulceration: one of these points had already perforated into the abdominal cavity, leaving an opening large enough to admit a probe; the other presented a discolored spot with thinning of walls and slight depression resulting therefrom. The superior cyst was smaller, sacculated, and filled with phosphatic debris and pus. This cyst marked the point where doubtless rested the blunt end of the hair-pin. By continued pressure this had produced thickening of the walls, and finally a sacculated cavity. At the neck of the bladder was a large, ragged de-

pression representing the spot where the stone rested. Constant pressure had set in action an ulcerating process, showing how nature was attempting to remove the obstacle through the vagina. The wire sutures approximated perfectly the vaginal surface, but the mucous membrane of the bladder was in no way approximated, as its ragged, ulcerated condition would not admit of such union. The edges of this ragged depression were full of small particles of phosphatic debris, showing that the stone had been crowded down with much force into the neck of the bladder. The kidneys each weighed five ounces. In both the pelvis was dilated to quite an extent, but there were no especial evidences of damage to the rest of the organ. The cortex was of normal appearance, other than showing a certain degree of congestion.

The sequence of events is an interesting one. A hair-pin slipped into the bladder through urethra; the two points became engaged in the mucous membrane and prevented its exit. Phosphatic crystallization about the hair-pin; ammoniacal urine and resulting cystitis. Stone grows large, almost concealing the pin. Bladder makes efforts to overcome the constantly increasing obstacle, assisted by abdominal pressure from the patient. The stone becomes a ball-valve dropping into the urethral orifice at base of bladder, and completely preventing exit of urine; by assuming knee-elbow position this ball is allowed to slip back and allow the passage of a little urine past it. In this way patient at last voided nearly all her urine. Pressure from without and within impels the fundus on to the blunt end of hair-pin, thereby causing thickening, rupture of inner wall, and formation of cyst. This double pressure causes also forcible backing of water up ureters into pelvis of kidneys, and this in turn produces dilatation of this part. Finally this constant backward pressure separates muscular walls of bladder at point of entrance of right ureter; nature resists by throwing out inflammatory coverings; a cyst develops which is firmly attached by these resisting inflammatory processes to the anterior wall of abdominal cavity. At last nature herself is overcome; she is trying to expel the obstacle through an extemporized path into the vagina, at the same time guarding against any such accident as rupture of the expelling parts; unable to meet this double duty, one weak point gives way; perforation occurs into the abdominal cavity, followed by shock, collapse, and death.

RECENT PROGRESS IN SURGERY.

BY A. T. CABOT, M. D.,

Surgeon to Boston Children's Hospital, Out-Patient Surgeon to Massachusetts General Hospital.

EXCISION OF THE KNEE-JOINT.

DR. G. E. FENWICK,¹ in a little monograph upon this subject, reports twenty-eight cases of excision done in the Montreal General Hospital since 1865, of which twenty occurred in his own service. He calls particular attention to his method of sawing the bones, which is to round off the end of the femur so as to be convex downwards, while the section of the tibia is made to form a concavity into which the end of the femur may be fitted. This procedure, he says, obvi-

ates to a great degree the tendency to antero-posterior displacement, and enables the operator to remove the whole articulating surface of the femur without encroaching on the line of the epiphysis.

Dr. Fenwick is very earnest in his praise of Dr. Watson's² splint for securing immobility after operation, which he says has all the advantages claimed by the inventor. He applies it, however, with a paraffine bandage instead of with plaster of Paris, as suggested by Watson.

Dr. Davy³ reports twenty-one cases of recovery after excision of the knee without a death. Of these patients only two were over fifteen years of age. He advocates the performance of excision in children, even when the epiphyseal cartilage has to be removed, on the ground that the shortened leg with a foot at the end of it is better than any stump. Dr. Davy endeavors to prevent antero-posterior displacement of the bones by a procedure similar to that employed by Dr. Fenwick, namely, by a sort of tenon-and-mortise joint between the ends of the bones.

TREATMENT OF MAMMARY CANCER.

Küster, in a paper read before the Twelfth Congress of the German Surgical Society, advocates the careful dissection and removal of the contents of the axilla in every operation for cancer of the mamma.

This recommendation, which is not new, gains weight from his report of the careful microscopical examination of the glands in a number of cases where they were seemingly unaffected, and in which, nevertheless, a commencing cancerous change was found in them.

To show the effect of this thorough operation in preventing recurrence Küster states that, of sixty women whom he had thus operated upon prior to three years ago, thirteen, or 21.66 per cent., remain well.

Gussenbauer, Langenbeck, and Esmarch spoke in favor of this thorough operation, and Esmarch even declared that when the glands were intimately adherent to the vessels and nerves, and yet there was no appearance of the disease in other parts, he was in favor of disarticulating the arm to permit of thorough removal; and he stated that the only case in which he had done this recovered, and has never had a return of the disease.

ON THE ENTRANCE OF AIR INTO THE VEINS DURING OPERATIONS.

Mr. Frederick Treves⁴ reports two cases in which, during operations upon the neck, air was drawn into the veins with an audible hissing sound. In both cases the wound was at once flooded with water, and firm pressure caused a bubbling up of air in considerable quantity in the wound. Both patients recovered. One was a child of two years, in whom tracheotomy was done for the removal of a foreign body; the other was a man of fifty, whose common carotid artery was tied.

Mr. Treves calls attention to the fact that the danger of this accident is imminent only when the wound is comparatively dry, as fluid in the wound effectually closes the orifices of the veins against the air. He advises, therefore, that during operations in dangerous proximity to venous trunks a sponge full of warm water be kept at hand to squeeze into the wound at

the first sign of danger. His cases would also go to show that by quick compression of the chest much of the air can be driven out of the veins again after it has entered.

COMBINED INTERNAL AND EXTERNAL OESOPHAGOTOMY.

Gussenbauer¹ reports two cases of stricture of the oesophagus, impermeable to the finest bougies, which he treated successfully by a method to which he gives the name of "combined oesophagotomy."

The oesophagus was first opened by the ordinary cut of external oesophagotomy; from there a probe and then a director was passed through the narrowed portion, and with a herniotomy knife, guided by the director, the stricture was incised anteriorly and somewhat laterally. A catheter was then passed into the stomach, and left there for the purpose of nourishment. Later some further dilatation by bougies was accomplished.

CASE I. A girl of twenty-six. Oesophagus extensively cauterized with sulphuric acid, taken with suicidal intent. Stricture extended from the level of the cricoid cartilage to about opposite the bifurcation of the trachea. After incision as described a catheter (No. 24 French) was passed, and before she left the hospital dilatation was carried to No. 36 French. She soon neglected to pass her bougie, and speedily came back with a stricture requiring the "combined oesophagotomy" to again overcome. Since this time the constant use of bougies has kept her throat permeable.

CASE II. Girl, two and a half years old. Tight stricture near cardiac orifice due to swallowing carbolic acid. Stricture dilated by method described till it would take a No. 30 French bougie. This is passed by the child's father once a week, and the stricture is thus kept open now, one year after operation.

In none of these operations was there considerable bleeding.

TREATMENT OF FRACTURE OF THE PATELLA.

Professor Lister² reports seven cases in which he has cut down upon and wired the fractured patella. Three of these cases were of recent fracture; in two the fracture had existed for one or two weeks, and two were cases of old ununited fracture.

All of the patients recovered with bony union between the fragments and with useful legs.

In some of the later cases the wire after being twisted was bent and hammered down upon the anterior surface of the patella, where it healed over and gave no subsequent trouble.

The ardor of reckless imitators may be somewhat damped by Professor Lister's remark, that he "considered no man justified in performing such an operation, unless he could say with a clear conscience that he considered himself morally certain of avoiding the entrance of any septic mischief into the wound."

REMOVAL OF GOITRE.*

Professor Kocher, of Berne, speaking of operative interference in the treatment of goitre, stated that since 1877 he had operated one hundred and three times for the removal of thyroid tumors.

The dangers most to be feared are the wounding of

the recurrent laryngeal nerve and the difficulty of avoiding and checking hæmorrhage. The incision employed was a curved one, and the vessels, both veins and arteries, were sought out and tied separately; this was the more easy as a certain regularity of distribution was noticed in the veins as well as in the arteries. Tracheotomy was avoided when possible.

Partial excision by the removal of one half of the thyroid tumor also has given satisfactory results. The portion of the tumor left has rarely shown subsequent growth or given inconvenience.

The trachea has been observed to become atrophied after total excision of a goitre, with ligature of the main arteries supplying the thyroid gland, owing to the fact that the inferior thyroid artery supplies the trachea with most of its blood.

Wölfler said that according to Billroth's experience it is wiser not to operate on thyroid tumors simply on account of the deformity, but that, on the other hand, if dyspnoea compels one to the operation, neither pregnancy nor advanced age are to be regarded as contraindications.

Billroth always makes his incision along the sternomastoid muscle and opens the capsule of the goitre.

In tying the inferior thyroid artery the recurrent laryngeal nerve is to be especially looked out for and avoided. If parts of the growth are left adherent to the trachea a recurrence is to be feared.

Maas urged against operating except in case of necessity, as in the greater number of goitres treated in the Freiburg Clinic a cure was attained by the internal and local use of iodine.

RADICAL CURE OF HERNIA IN CHILDHOOD.

Mr. Pughe⁴ advocates the treatment of large herniæ in children by what he terms "the open method." This consists of the usual operation of herniotomy with ligature of the sac at the internal ring.

The steps of the operation are as follows: The sac is uncovered by an incision commencing a little above the internal ring and running down over the hernia for about three inches. "The sac is then separated from the cord and freed from surrounding structures, and a ligature of chromicized cat-gut is passed round it with an aneurism needle. The contents of the hernia being now returned to the abdomen and the sac drawn down, the ligature is tied once or twice round its neck as high up as possible. Lastly, the sac must be incised and drained.

To quote from the author: "The all-important point undoubtedly is to firmly and securely ligature the sac at the inner ring, that is, at the part where it becomes continuous with the general cavity of the peritonæum, so as to make the peritoneal surface perfectly level over the internal opening into the canal. The depression over the internal ring is thus obliterated; and by preventing the hernia from descending into the sac and dilating the canal after the manner that the bag of membranes acts on the os uteri, the evil is cut off at its very root, as it were, and the tendency towards a reformation of the hernia is entirely done away with."

— The *Sanitarian*, after a year's experience as a weekly publication, announces a return to its old form as a monthly, but enlarged to ninety-six pages, and with improved type.

Hospital Practice and Clinical Memoranda.

GENERAL TUBERCULOSIS AS ONE OF THE SEQUELÆ OF TYPHOID FEVER.

BY GEORGE H. LYMAN, M. D.,
Visiting Physician Boston City Hospital.

THE following case presents some features of interest in the way of diagnosis, it being an instance of rapid development of tubercle in serous membranes, with no positive pathognomonic symptoms. The autopsy as recorded by Dr. Gannett revealed chronic fibrous pachymeningitis, tuberculosis of pia mater, peritonæum, pleura and lungs, also chronic diffuse nephritis, fatty infiltration of liver, fatty degeneration of the intima of the aorta, and perforation of the intestines.

Anna W——, aged twenty-three, a widow, delicate, but fairly healthy looking, was sent to the City Hospital, October 5th, as a case of "threatened miscarriage, complicated with typhoid." Both parents died of phthisis. Excepting scarlatina and diphtheria had never had any severe illness. Never had children. Two miscarriages, the last two years before entrance, since when she has been subject to dragging pains in the loins. Menses always irregular, often delayed for two or three months; flow and pain moderate. Her last period was two months ago. Has now some slight flowing; ceased following day. She says that about the middle of September she began to have headache, backache, general malaise, and chilliness with marked prostration, confining her to her bed. For a week has had some diarrhœa with colicky pains, no tenesmus, and dejections free from blood and mucus. Says she has had some vomiting, slight sore throat, and hacking cough, without expectoration. Has always been troubled with slight palpitation, dyspnea, and œdema of ankles. Her appetite is poor, and she is restless at night. Micturition normal. On examination no marked pulmonary symptoms. Soft systolic murmur at base of heart. No headache. Tongue clean and moist. No rose spots nor epistaxis. Tenderness in left iliac region. No gurgling. Considerable tympany, but no tenderness on pressure. Temperature 99° F.; pulse 118.

There being some doubt as to her antecedents it was for a day or two thought possible that another miscarriage was impending.

October 10th, five days later; no flowing nor signs of pregnancy. Temperature 102° F.; pulse 110. Has vomited but a few times since entrance. Tympany still continues; but she makes no complaint of it nor of the weight of the stupes and fomentations. Legs not drawn up. She has three or four loose yellow dejections daily. The skin is always soft and warm. Says she is quite comfortable, and in fact she has made no complaint at the daily visit of pain. Is always cheerful, and says she is doing well.

The daily temperature, the tympany, and the continuance of the thin yellow dejections, in the absence of any other recognizable cause made the diagnosis of typhoid with which she entered the hospital most probable. On the 14th, four days later, her morning temperature was 102° F.; pulse 140, and becoming more feeble. Tympany unchanged; anæmia more marked; hæmorrhage feared. On the 18th complained for the first time of slight pain in right side of chest; no cough; a friction rub was discovered.

October 19th. Temperature rose to 103.2° F.; pulse 152.

October 26th. Pulse during last week about 130; temperature varying from 100.2° F. to 103.2° F., five-grain doses of quinine having no perceptible effect.

October 28th. Looks better; pulse 120; temperature 99.2° F.; abdomen less tense; has always taken nourishment well, though quite indifferent to it, but to-day she asks for more food.

October 31st. Morning temperature rose to 104.2° F., with a rigor, but in evening fell 6.6° F. to 97.6° F.

November 7th. Had a chill day before yesterday, and again this evening, with slight hæmorrhage from the bowels.

November 9th. Involuntary dejections; complains of nausea and objects to nourishment.

November 11th. Mild delirium for thirty-six hours; at five A. M. took brandy and water without trouble, and in ten minutes was found dead.

There are two ways of looking at this case. We have here a patient who, previously in good health, after two months of illness without any positive pathognomonic symptoms, dies of the effects of extensive tuberculosis. During life, with the exception that a typhoidal element complicated her case, there was nothing to justify a positive diagnosis. Until two days before her death she was cheerful, complained of no pain in particular, took and digested a fair amount of nourishment, slept fairly well, had no pulmonary or cerebral irritation. The principal symptoms, exclusive of some long standing uterine disturbances, were exaltation of pulse and temperature, abdominal tympany, and anæmia. For the first three weeks, and before her entrance to the hospital, they were apparently those of a mild typhoidal attack (and in the absence of any better history one is tempted to so consider it). In this view the general tuberculosis may be looked upon as a not improbable sequence, her parents having died of phthisis. Its rapid development without more definite signs is sufficiently noteworthy as one of the not very common sequelæ of typhoid fever.

Liebermeister states that out of two hundred and fifty autopsies after typhoid this condition was found four times only. His presumption is that such cases occur in persons who have the specific poison of tubercular phthisis lying latent within them, and that the fever with its sequelæ only serves as an exciting cause for the development of these processes. He also alludes to the fact that miliary tubercle may be developed in the pia mater (and presumably elsewhere) without a single symptom leading to suspicion of its existence.

But, on the other hand, the autopsy in this case reveals no evidence of typhoid, and the question arises was not this a case of tuberculosis *ab initio*.

What the chart was for the three weeks before entrance in the early stages of the disease we have no means of knowing, and from the date of entrance it gives us little help. It resembles any other in which complications have ensued after the typhoidal poison may be supposed to have been eliminated. There was no history of rose spots or epistaxis, and the tongue was so entirely clean and natural as to excite constant remark.

That the post-mortem appearances in an ordinary case of uncomplicated typhoid fever are decisively characteristic is undoubtedly true, but milder abortive cases resulting in recovery leave us of course without this

positive method of confirming the diagnosis. In these abortive cases, however, such perhaps as the one now reported, where a subsequently fatal result is directly due to some complication, excited to active development by the primary febrile condition, all anatomical evidences of which may in the mean time have disappeared, is the absence of these ordinary post-mortem signs conclusive as against typhoid.

Is it true that the agminated or solitary glands or follicles in cases of abortive typhoid, where there is probably but a slight degree of infiltration, never so far return to their normal condition as to remove all anatomical evidence of previous disease. Liebermeister says: "When the infiltration extends only to a moderate degree, the swelling may gradually diminish by degeneration and absorption until the patches and follicles return to their normal condition." Friedrich also, as quoted by Aitken from the *British and Foreign Medico-Chirurgical Review* for July, 1858, on the Enteric Fever of Children, holds that the infiltrated follicles or vesicles, either from the resorption of the infiltrated material or more often from rupture into the intestinal canal, revert to a normal condition without the formation of any cicatrix.

PROBABLE PROGRESSIVE HÆMORRHIAGE INTO BOWEL DEPENDING ON GENERAL DISORGANIZATION OF THE BLOOD.¹

BY R. M. HODGES, M. D.

MRS. —, aged twenty-eight, mother of two children, and who, though never robust, had been in better health than usual during the past winter. Dr. Hodges was asked to see her at his convenience, as she was not feeling very well, although out and about as usual. At his first approach to her bedside he was struck by the extreme lividity of her countenance, which reminded him of cholera cases. The tongue and fauces even were black, but the throat presented nothing otherwise unnatural; the pulse was good; breathing quiet and calm; auscultation and percussion normal. No local cause for the condition could be detected, and there was no explanation of the appearance presented by the patient to be derived from her previous history. The only complaint made was of an annoying pain when, as she said, she hiccupped; the "hiccup" being in reality the eructation (in a very moderate degree) of gas from the stomach. An hour later attention was called to the patient's urine. But little had been passed during the night, and the specimen shown was less than half an ounce, and black like that in cases of carbolic-acid poisoning. It was examined by Dr. E. S. Wood in less than an hour after it was passed, and contained one fourth per cent. albumen, numerous brown, granular casts, and much blood; the specific gravity being 1012. This suggested acute nephritis, and dropsy was expected, but it never came. In the afternoon there was a large, black, tarry dejection, not seen except by the nurse. Dr. M. Wyman, of Cambridge, visited the patient in consultation on the first day of her sickness.

The urine of the second day, also examined by Dr. Wood, contained no blood, but an immense amount of

blood pigment in solution, and a large quantity of serum albumen. Otherwise the same general characters remained. The patient's symptoms were unchanged, though the lividity had diminished. There was occasional nausea. She had one loose black dejection. There was considerable thirst, and simple food was relished. Dr. Wyman again saw the patient in consultation.

On the third day the urine regained its natural color and the crystals of hæmatin disappeared. But one granular cast was found in a careful examination of five slides. The amount of albumen had, however, increased. The patient complained of severe headache, as well as of pains about her waist, first on one side, then on the other, but they were never severe, nor was their nature comprehensible. Her color continued to improve, and she took milk, beef tea, jelly, and champagne with much satisfaction. She had one dejection similar to that of the day before. Her intelligence and cheerfulness were not disturbed.

On the fourth and fifth days there were ten black and bloody dejections, some of them mixed with a good deal of transparent mucus, for which ergot and bismuth were given, and with apparent success, so far as the evacuations were concerned. The general condition continued about the same, and on each of these days she took and relished a chop, and some broiled chicken.

At the end of the fifth day she began to have dyspnoea and rapid breathing, and was restless during the night. This condition was first seen by the speaker on the morning of the sixth day, when the complexion had become sallow and the lips pallid. An eighth of a grain of morphia had been given the evening before, but this was thought to have nothing to do with the disturbed breathing, as she had taken it on other occasions without any unpleasant effect. The respiratory and cardiac sounds continued perfectly good, and at her solicitation the patient was placed in a chair for an hour at noon, as a relief to the restlessness and dyspnoea. In the afternoon some slight râles were detected in the *front* of the chest, the respiration and percussion being elsewhere natural; the pulse fell from the seventies into the sixties, the heart sounds grew faint, the temperature went below normal, weakness increased, and death occurred at night. Dr. Wyman again saw the patient on this day.

At no time during the patient's illness did the amount of urine passed in twenty-four hours exceed two ounces. The temperature never rose above 98° F. She had very fair sleep at night, until that of the fifth day. There was never any somnolency or delirium, or any abatement of her cheerfulness and intelligence until the afternoon before her death. The increasing pallor, together with the other symptoms which have been narrated, suggested that the fatal result was due to a progressive hæmorrhage into the bowel, apparently owing to some general disorganization of the blood itself. There were no purpuric spots. Careful inquiry failed to obtain anterior evidence of any chronic renal symptoms, or other organic affection, or of any possible and recent drug poisoning. The patient had been frequently under the care of Dr. Hodges.

The treatment pursued was stimulating, supporting, anodyne, and expectant. Packing with blankets wrung out in hot water, and counter-irritation with mustard, were resorted to for the suppression of urine.

There was no autopsy.

¹ Read before the Boston Society for Medical Improvement, May 14, 1883.

Reports of Societies.

PROCEEDINGS OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. SUCKINGHAM, M. D., SECRETARY.

DECEMBER 10, 1883. DR. CHARLES D. HOMANS presided.

DR. C. B. PORTER presented a specimen from a case of

OLD STRICTURE, MULTIPLE ABSCESS, PERINEAL SECTION, SEPTICÆMIA, DEATH.

E. S. R., aged forty-three, entered hospital November 28th. Stricture for many years. Eight years ago had it divulsed at Massachusetts General Hospital. Four years after, having failed to pass sound as directed, had recontraction with urethral rupture, urinary infiltration, and abscess in perinæum. Perineal section was performed outside the hospital, from which he recovered. He was again neglectful of passage of sounds, and the stricture recontracted. About six months ago had fresh infiltration. At entrance to hospital he passed a stream the size of No. 6, French scale. The examination of perinæum shows a typical "watering pot" perinæum; there are several fistulae, the result of old abscesses, and at junction of left thigh with perinæum is an abscess the size of a goose egg. The whole perinæum from scrotum well back towards the anus is inflamed, tender, and infiltrated. The abscess was laid open and syringed out with an antiseptic solution. On the following day, November 31st, a small-sized bougie, No. 6, French, was passed, and, fortunately, entered the bladder. It was retained in the urethra until the following day, when perineal section was performed with the bougie as a guide. The tissues of the perinæum were very dense and hard, infiltrated with pus, exceedingly foul and offensive. A catheter, size No. 23, French, was passed, and fastened in the bladder with a tube attached emptying into a receptacle by the side of the bed.

December 2d. Patient fairly comfortable; passed a good amount of urine; temperature, however, 104.8° F.

December 3d. Temperature 104°+ F. Complained of pain all over. Wound looked well. Syringed with carbolic solution every morning.

December 4th. Temperature 102.6° F.; nausea and vomiting. Quinine, two grains, every three hours; whiskey, half an ounce, every two hours. Examination of urine by Dr. Wood. Specific gravity 1023; reaction alkaline; albumen, one fourth per cent.; sediment excessive; pus; considerable blood; urethral cells; occasional hyaline and granular casts.

December 5th, four days after the operation, patient restless, tossing in bed; pulled the catheter out; skin hot and dry; temperature 102.9° F. Very little urine secreted. Pilocarpine, one sixth grain, subcutaneously, and repeated in twenty minutes, produced free diaphoresis. A drachm of brandy given every half hour. Temperature at night 104.9° F.

December 6th. Condition about the same. Only takes very little nourishment. Urine diminished very much. Spotted appearance very generally diffused over skin; slight twitching of hands and feet; lies in a stupor from which he is easily aroused; pulse 150, weak and feeble, and somewhat irregular; has had involuntary dejections.

December 7th. Passed a fairly quiet night. Throat

very dry, and voice husky; talks with difficulty; eyes have glazed and vacant look. Refused to take nourishment after eleven A. M.; breathing became very labored; pulse very rapid and almost imperceptible. Died about two P. M., sixth day after operation.

Autopsy made by Dr. R. H. Fitz, twenty-three hours after death.

Diagnosis. Chronic adhesive pleurisy. Cheesy broncho-pneumonia. Interstitial pneumonia. Cloudy swelling of heart, liver, and kidney. Acute splenic tumor. Old cicatrix of right kidney. Hemorrhagic cystitis. Pyelitis. Stricture of urethra with perineal fistula and perineal incision. Acute septicæmia.

DR. PORTER called attention to the continuous high temperature. It was never much below 103° F. after first going up. He said that he felt confirmed by this case in the belief that, in addition to free drainage, injections, and sprinkling with iodoform, cases of perineal section should have a daily sitz-bath of phenyle lasting from twenty-five minutes to half an hour, enabling the parts to fill up with lotion to an extent that injections will not accomplish. This he had formerly done, and he would never again omit it until he had proof that it did no good. Every urethral surgeon knows that a cut or even the passage of a bougie in a patient with pyelitis or cystitis may cause fatal shock or other grave symptoms. Dr. Bigelow had told him of a death occurring in twenty-four hours from taking a gutta-percha cast of the urethra. Where the urine is alkaline the speaker thinks there is much more danger than where it is normal.

DR. G. H. LYMAN read the regular paper of the evening, —

GENERAL TUBERCULOSIS AS ONE OF THE SEQUELÆ OF TYPHOID FEVER.

Dr. Lyman said that he did not regard the diagnosis as certain. He had presented the case in order to call out a discussion. These cases usually appear at the hospitals with unsatisfactory and inaccurate histories of the previous symptoms. This patient had a very clean tongue, but everything else about the case suggested that the tuberculosis was a sequel to mild typhoid.

DR. W. W. GANNETT said that he thought that the existence of tuberculosis accounted for the symptoms. The diagnosis is a question of definition. If typhoid is an enteric fever with certain lesions he failed to see its presence. He had met with five or six cases of miliary tuberculosis in which the diagnosis of typhoid had been made during life, and spoke of the extreme emaciation and the fact that they neither got better nor worse for some time. Typhoid patients either get well or they die.

DR. LYMAN said that typhoid does not always get well at a regular period. It may last six or eight weeks with continued high temperature, and then end in recovery. He thinks, however, that these prolonged cases are those in which we are most likely to find complications, but that we do not always do so.

DR. O. W. DOE remarked as follows: There is no doubt that this was a case of acute tuberculosis, and the question at issue is whether it was such *ab initio* or was a sequel of typhoid fever. It seems to me much more likely the former, the symptoms most manifest being those of tubercular peritonitis. The autopsy shows no lesions which can be referred to typhoid excepting the perforation, but this is often seen in tuber-

cular peritonitis. Bristow, in his article on this disease in Reynolds' System of Medicine, says we find here strong fibrous bands consisting of lymph, which have assumed the form of connective tissue, and in these bands large masses of tubercles are seen which frequently invade the intestinal walls, and lead to ulcerations from without. The symptoms of tubercular peritonitis are almost the same as those of typhoid fever as given by Dr. Harley, excepting that in peritonitis the tongue is usually moist and clean, exactly the condition that Dr. Lyman particularly refers to in his case. There are also tympanites, abdominal distention and tenderness, and diarrhoea. Tuberculosis is developed *ab initio* in anæmic and debilitated patients with a hereditary predisposition to the disease, and this was the condition Dr. Lyman's patient was in, owing to her previous miscarriages; whereas, when it occurs as a sequel to typhoid, both Hirschfeld and Ruehle concur in the opinion that it arises from the absorption of the matter of typhoidal ulcerations. Now in Dr. Lyman's case the disease from its earliest manifestations lasted only about two months, and it seems hardly possible that the anatomical lesions characteristic of typhoid and severe enough to infect the system with so general a tuberculosis could have wholly disappeared in so short a time.

DR. LYMAN said that he supposed that a latent tuberculosis might be developed by the febrile condition.

DR. GANNETT answered to a question of Dr. Doe, that the oldest signs of tubercle were in the uterus, from which the disease had penetrated through the tubes to the peritonæum. The ovaries had become adherent to the intestine. Tubercle existed all over the peritonæum, but he found no evidence of it in the mucous membrane of the intestine. It was found in the pleura, which it had possibly reached through the diaphragm, and also in the brain.

DR. GEORGE B. SHATTUCK said that he had seen Dr. Lyman's patient several times at the City Hospital, when the diagnosis of typhoid fever had been suggested. Considering the whole history of the case in the light thrown upon it by the autopsy, he thought acute miliary tuberculosis a sufficient explanation without the addition of typhoid fever. The general subject and the case itself were both of much interest, and he was glad Dr. Lyman had brought them before the Society.

The presence of nodules of caseous metamorphosis in the lungs and intestinal glands, as well as in the lining membrane of the uterus, as reported in the full record of the autopsy, would seem to indicate an older process preceding the acute attack; an assumption favored by the family history, and in accord with the theory attributing the origin of acute tuberculosis in many cases to auto-inoculation from such points of caseous degeneration. On the other hand, it was undoubtedly true that acute tuberculosis did at times present itself in individuals apparently enjoying good health until thus attacked, and neither anæmic nor debilitated. The tendency to regard cases of acute tuberculosis as typhoid fever was not only common, but natural, and often unavoidable. The chart in Dr. Lyman's case illustrated to some extent a point in the differential diagnosis suggested by Wunderlich, which was also shown by a clinical chart of a patient under Dr. Shattuck's care at the City Hospital two years before, which he passed around. That case had been supposed to be probable typhoid until the diagnosis of

acute tuberculosis was established by the autopsy. The point alluded to was the disproportion between a very rapid pulse and respiration, and a comparatively low range of temperature, — between a pulse ranging from 120 to 160, with a respiration from 30 to 50, and a temperature not rising above 103° F., or 103.5° F. The higher temperatures in the reported case apparently corresponded with periods when rupture took place into the intestine.

DR. E. G. CUTLER thought that little remained to be said after the previous remarks. To one unfamiliar with the details of the case a diagnosis of primary tuberculosis would seem more natural than one of typhoid fever with the latter as a sequence. As has been stated, the differential diagnosis between the two diseases was oftentimes most difficult. A case had occurred to him at the Carney Hospital where typhoid fever was at first diagnosticated, but persistence of the fever and irregularity of the symptoms forced a change in diagnosis to tuberculosis, and an autopsy proved the correctness of the subsequent view. While a house officer at the Massachusetts General Hospital he had seen a similar case.

DR. H. I. BOWDITCH said that he had never seen miliary tuberculosis follow undoubted typhoid, so far as he remembered. He had seen it in doubtful cases. He spoke of the importance of inquiring into the early history at a first examination; especially as to previous health and the presence or absence of cough. Also of the importance of the physical examination of the lungs, and of the rate of the pulse. He thought there was a tendency to make the diagnosis of typhoid unwarrantably, it being one of our prominent diseases.

DR. GEORGE C. SHATTUCK said: This report is a very interesting one, as many questions of importance are raised. The diagnosis between typhoid fever and tuberculosis has seemed to me at times difficult. And yet in their ætiology they differ. Ought we not to look upon typhoid fever as the manifestation of a zymotic poison, the action of which in the different organs and functions differs in individual cases. True, the lesion of Peyer's patches is regarded as the anatomical characteristic; the disease is sometimes called enteric fever; and yet must we not give the name of typhoid when this lesion is not found after death, and when there are no symptoms of abdominal disease during life? The so-called typhoid symptoms are those of septicæmia. In many, and we may say in most, cases there is destruction of tissue by ulceration, and dead animal matter lies in proximity to veins and absorbents. Are not relapses in typhoid fever due to septicæmia?

Then tuberculosis is a constitutional disease, attended in some cases with dothinenteritis, in others with pulmonary lesions, from which animal poison readily enters the blood. The anatomical characteristics of tuberculosis are found in different parts and organs, whose functions are variously interfered with. I had a case of tuberculosis many years ago where the symptoms were those of marasmus and dyspepsia, where typhoid fever was never suggested, and where no ulcerations were found after death. I have now a patient under treatment where the diagnosis is tuberculosis, and diarrhoea has been a prominent symptom, but where typhoid fever is not suspected.

I should regard the case reported as one of tuberculosis, though I am not surprised that others are disposed to refer some of the symptoms to typhoid fever,

nor that the diagnosis of typhoid fever was made when the patient entered the hospital.

DR. G. B. SHATTUCK, replying to Dr. Bowditch, called attention to the fact that in acute tuberculosis pulmonary signs are either conspicuous by their *absence* or represented merely by a short cough, most noticeable in the early part of the attack, whereas the bronchitis of typhoid fever comes at a later period. Hospital patients, it should be remembered, are, generally, not seen in the first days. In his own case, previously referred to, there was a complete absence of physical signs in the chest. A differential diagnosis between a typical case of typhoid and a typical case of acute tuberculosis should be easy, but typical cases of disease existed rather in the books than in the wards, and certainly a typical clinical picture of typhoid fever was the rare exception. There may be diarrhoea in tuberculosis and constipation in typhoid fever; abdominal tenderness and a moderately enlarged spleen in each; and Bartholow, as well as Jaccoud, speaks of an occasional eruption, not unlike the roseola of typhoid, as having been observed in acute tuberculosis.

As to duration of disease, referred to by Dr. Gannett, tuberculosis may last any length of time, from two weeks to eight, and typhoid fever the same. Flint mentions only one case of tuberculosis in his experience with so short a duration as eleven days.

DR. LYMAN was of the opinion, with the previous speaker, that the typhoid fever of the books is the exception in the wards. It is by no means unusual to see a dozen cases together without a dry tongue. A typical temperature chart is a rare thing, although it is always ground for suspicion if we do not get regular remissions during the first few days. More often we get the peculiar exaggerated remissions toward the close. Constipation is not uncommon. Rose spots may be absent. In the reported case the lungs had been examined when she entered the hospital, with negative results. It was not until the last few days that friction sounds were heard in the pleura. Unless Dr. Gannett could say that tuberculosis was of too old standing, he did not see why it could not be developed by typhoid. We know how typhoid does develop previously latent diseases. As to the absence of anatomical lesions, we have no opportunity to verify the diagnosis of abortive typhoid by post-mortem examination, because the patients get well. He could not see why if changes occur in the follicles in cases of mild typhoid, not resulting in ulceration, they might not be absorbed.

DR. GANNETT said that the use of the term typhoid depends on whether we adopt a symptomatic or an anatomical nomenclature, and that the anatomical classification, while open to objection, has been generally accepted as the best practicable. Granting this, typhoid is a disease of Peyer's patches and the solitary follicles. Allow that most of the products of disease may be absorbed, and assume that there are no cicatrices, there still remain the so-called shaved beard appearances, small areas of pigment that remain through life even after the intestinal catarrh of children.

In answer to Dr. Lyman, Dr. Gannett quoted the statement of Virchow, made four years ago, that the diarrhoea of typhoid depends on catarrh of the mucous membrane of the intestine, and has nothing to do with ulceration. Dr. Gannett said, in closing, that one point in diagnosis is the presence of tubercle in the choroid of the eye, which, however, is by no means constant.

DR. G. B. SHATTUCK asked Dr. Gannett whether he regarded the presence or absence of the intestinal appearances alluded to as being sufficiently specific and constant to justify testimony in a court of law as to an individual's having been or not been attacked with typhoid fever at any period previous to death, however remote.

DR. GANNETT answered that if absolutely nothing were found he would not be justified in denying that a mild typhoid had existed at some previous time, because it is possible the contrary may sometime be proved.

DR. A. H. NICHOLS spoke of the analogies and differences between the typhoid state which accompanies several distinct diseases and the specific disease known as typhoid fever. He had observed, during a period of years at the sea-shore, a considerable number of severe illnesses, the result of septic infection induced by drinking water contaminated with faecal matter, where the symptoms were of a typhoid character. As in typhoid fever, there was a prolonged period of incubation, followed by continued high fever, prostration, insomnia, headache, with dry, brown tongue, and occasional ecchymosis. Instead of diarrhoea, however, there was usually constipation, while the characteristic thermal curve pointed out by Wunderlich, as well as the so-called rose spots, were invariably absent.

The well-known causes of infection in these cases, as well as their uniform clinical history, all indicated the diagnosis of an artificial *septic fever*, having no real connection with true typhoid fever.

Recent Literature.

On the Treatment of Wounds and Fractures. By Sampson Gamgee, F. R. S. E. Philadelphia: P. Blakiston, Son & Co. 1883.

This second edition of Mr. Gamgee's Clinical Lectures contains the substance of his work on the Treatment of Fractures, 1871, and on the Treatment of Wounds, 1878.

Mr. Gamgee preaches that cleanliness, exact coaptation of parts, and efficient immobilization are the important aids which a surgeon can afford to wounded tissues, whether soft or bony, and that protection from atmospheric or other germs is a matter of little importance.

The value of compression and fixation in restraining and dissipating inflammatory conditions is constantly urged and illustrated.

The simplicity of the treatment advocated is certainly a great and evident recommendation. Mr. Gamgee's dressing materials are styptic colloid to check oozing, absorbent cotton to provide for elastic pressure and to absorb discharges, strips of mill board to secure fixation and equalize pressure, and a roller of absorbent cloth to fix cotton and board in place. With these materials he treats compound fractures of the most serious nature, and, to judge from the illustrative cases, with excellent success.

The book will bear very careful reading, which indeed its interest invites, and the student cannot fail to get much valuable suggestion from it.

In regard to Mr. Gamgee's attitude towards antiseptic surgery some exceptions may be taken. He seems to fall into the error of confounding the use of

carbolic acid in wounds with the practice of antiseptic surgery, and while criticising the use of strong antiseptic washes, and expressing dissent from the idea that it is necessary to guard against the entry of germs from the air, he appears to overlook the antiseptic character of his own dressing.

The thorough application of styptic colloid or compound tincture of benzoin to a wound which is then immediately covered with absorbent cotton (the most efficient protection possible against outside impurities) is certainly a decidedly antiseptic procedure, and the successful treatment of wounds in this manner does not offer very convincing evidence of the innocuousness of atmospheric germs.

Enteric Fever, its Prevalence and Modifications; Ætiology; Pathology and Treatment: As Illustrated by Army Data at Home and Abroad. By FRANCIS H. WELCH, F. R. C. S., Surgeon-Major. Philadelphia: Presley Blakiston, Son & Co. 1883.

Surgeon-Major Welch, of the British army, received the Alexander Prize in 1881 for an essay of which this book is a modification. Army surgeons undoubtedly enjoy certain advantages in the study and observation of some diseases which are not possessed by the medical man in civil practice, even when attached to a hospital. The antecedent and immediate surroundings and conditions to which soldiers have been or are exposed can often be more accurately defined than this can be done for the civilian population, and the same material may be studied by the same observer under varying conditions. This is especially true of such a disease as typhoid fever, as manifested among British troops at the different stations which they occupy in all parts of the world. The intelligent and zealous army surgeon may find here a field in which his spare hours can be spent to his own satisfaction and to the profit of medical science.

The present book is an octavo volume of nearly two hundred pages, with table of contents and index. The army statistics of typhoid fever embrace those of the British islands and of twenty-two foreign and colonial countries in all parts of the world, from 1860 to 1878, inclusive. The writer's figures and observations seem correct and careful, and not elaborated in support of a preconceived theory, and his conclusions we believe are sound. More than one half of the book treats of the ætiology of typhoid fever, and the writer's material leads him, as it must help to lead the reader, to the legitimate conclusion that the disease is a specific one, having its own specific poison.

We quote the following paragraphs from the last page of this section: "Let any individual cognizant of the disease in one country place his observations against others in other climates and sections of mankind; let him compare the results of diseased action, derived from different countries and at different times by different observers; and then putting all theory aside let him ask himself the question, is it within the range of experience, probability, or possibility, for such identical structure lesions to have been brought about by several and dissimilar causes? There can be no doubt of the answer to a question under like conditions in the physical, animal, and vegetable world. Hence, then, the conclusion arrived at is, that the specific theory more closely embraces the military data than any

other, and is the only one which meets the requirements of the facts."

Such a view of the ætiology is supported by the pathology, which offers the same manifestations in all countries under the most varied influences of soil and climate.

Dr. Welch remains a disciple of the expectant treatment, the treatment of symptoms as they arise in the individual case. He is a strong advocate of the disinfection of stools, but believes it to be insufficient as ordinarily attempted with such agents as carbolic acid and chloride of zinc, and advises the application of a high temperature as the only reliable germ destroyer.

Types of Insanity. An Illustrated Guide in the Physical Diagnosis of Mental Disease. By ALLAN McLANE HAMILTON, M. D. New York: William Wood & Co. 1883.

This book is made up of two parts, the first one being a description of physical appearances, conditions, and symptoms manifested in the insane, as well as a description of the proper method of examination of insane persons and abstracts from the lunacy laws of various states; and the second one a series of ten illustrations, all but one representing "types of insanity."

The author is evidently a devout believer in the physical theory of insanity, even going as far as to say that "Disease of the brain makes itself known by well-marked bodily symptoms, that are in themselves almost as important as the many variations of disordered mental action." The reviewer would be the last person to underrate the importance of bodily manifestations in mental disease, but at the same time sees no reason or occasion for regarding many of them as anything more than "variations of mental action."

The first part of the book is written in a light and sketchy manner, being little more than an outline of the subjects which it treats. It would have made the work more valuable to have omitted the chapters on Examination of Insane Persons, and Abstracts of Lunacy laws, and have devoted the space and time consumed in their preparation to the elaboration of the first chapters.

The second part is decidedly the best. The "types of insanity" are some of them really types, such as the idiot, for example. Others no doubt represent typical cases of mental disease, but have nothing in their appearance to distinguish them from types of sane faces. Plate IX. represents the face of a general parietic "demented and stupid." It looks to the writer like the face of an intelligent young laborer in robust health. Plate VIII. represents the face of a dement, "dirty, stupid, and careless." It would pass very well, however, for a picture of Napoleon we have seen, which portrays the hero buried deep in thought and in his coat collar. Almost all of the other faces in the plates look like those of lunatics or criminals, but it would be almost impossible to say exactly *what* forms of insanity they stand for.

Though it is a little difficult to understand the precise object of Dr. Hamilton's book, which is too full of elementary details for the specialist, and not full or thorough enough for the student in any particular, we nevertheless are glad to welcome it, as it indicates a desire on its author's part to throw additional light on that least understood of all diseases, — insanity.

A Treatise on the Diseases of the Nervous System. By JAMES ROSS, M. D., LL. D. Second Edition. 2 vols. New York: Wm. Wood & Co. 1883. Pages xxi., 1028, ix., 1047.

A second edition of this treatise has appeared very soon after the first. The work has been enlarged by nearly five hundred pages. As the author says, every page seems to have been subjected to careful revision; some parts of the old edition have been abridged, much new matter has been added, copious references to authorities and other authors have been inserted, adding much to the value of the work.

Under General Symptomatology the subject of Sensations is more fully elaborated, also several portions devoted to considering motor mechanisms.

The section in which the Deep Reflexes is considered has been rewritten, the patellar tendon reflex (called now "knee jerk") is no longer considered to be a true spinal reflex, but, taking the view advanced by Westphal in his later writings, it is referred to a local action upon the muscle; and the reaction is thought not to occur unless a certain degree of *tonus* is maintained in the muscle, and the reflex influence is necessary for the maintenance of this condition.

A subsection on Progressive Multiple Neuritis has been added. This, though short, gives a very good description of the affection, which has lately attracted considerable notice.

Much new matter has been added to the section on Diseases of the Ocular Motor Nerves, making that section more complete and valuable.

In the clinical portion of the work the most extensive addition has been made to Spastic Hemiplegia of Infancy and Athetosis; a description of Spasmodic Paraplegia of Infancy is given. Most of the additional matter in this section is reports of cases.

The above are the more extensive and important changes. The work can be recommended more especially for its careful review of the anatomy and physiology of the nervous system. As a whole it has the same excellences as the earlier edition, and there are fewer defects.

Elements of Histology. By E. KLEIN, M. D., F. R. S., Joint Lecturer on General Anatomy and Physiology in the Medical School of St. Bartholomew's Hospital, London. Illustrated with 181 engravings. Philadelphia: Henry C. Lea's Son & Co. 1883.

We are much disappointed to find that this little book contains nothing on the preparation of the tissues. It is full of wood-cuts taken from the author's Atlas of Histology and Handbook for the Physiological Laboratory, with many additional cuts. It is a very good compendium of histology.

Sea-Sickness: its Cause, Nature, and Prevention without Medicine or Change in Diet. By WILLIAM H. HUDSON. Boston: S. E. Cassino & Co. 1883.

This little book is written in a pleasing style, and furnishes many interesting reminiscences of the author's life on land and sea. To the physician it offers little of interest beyond adding one more to the long list of remedies, each of which has proved successful in the hands of its discoverer. The remedy consists

in the perfect relaxation of the muscles. The writer states that previous treatises on sea-sickness afford no light nor guide upon the subject. It is to be feared that his own work must be placed in the same category. Certainly any and all of the theories previously offered are more satisfactory than one which would locate the disturbance in the voluntary muscles. The physiological arguments upon which the remedy is based are extremely fanciful, but its efficacy is easily tested by experiment.

How to Examine the Chest. A Practical Guide for the Use of Students. By SAMUEL WEST, M. D., Oxon., M. R. C. P., Physician to the City of London Hospital for Diseases of the Chest, etc. Philadelphia: Blakiston, Son & Co. 1883.

This little book contains the substance of lectures delivered by the author at St. Bartholomew's Hospital, during the course of the demonstrations, which it has been his duty as medical tutor to give to the students during the last few years, by way of preparation for clinical work in the medical wards.

In it will be found a clear, concise statement of what is necessary for a proper examination of the chest. The nomenclature is simple, as it always should be in any elementary treatise on auscultation and precussion, and all discussion of theories of sound-production have been omitted. The sphygmograph receives due consideration, and the manual as a whole is certainly a very good one.

The Treatment of Wounds. By LEWIS S. PILCHER, A. M., M. D. New York: William Wood & Co. 1883. 391 pages.

In this volume of Wood's Library of Standard Medical Authors Dr. Pilcher gives quite a thorough description of the modern treatment of wounds, considering not only dressings proper, but also the methods of investigating wounds, of arresting hæmorrhage, and providing for rest of the injured parts.

The principles of treatment advocated are those of the modern antiseptic school, and several of the methods in use are described, and the range of usefulness of some of the usual antiseptic preparations is considered.

The strictly absorbent dressings, which without antiseptic properties act by their power of keeping the wound dry and removing from it the fluids which if left might putrefy, are passed over lightly.

Without containing anything of importance which is new, this book furnishes a convenient résumé of surgical wound treatment of the present day, which, however, will soon be much modified if the present rapid progress in this branch of our art continues.

— Johns Hopkins University has provided itself with a new gymnasium, which was lately opened to the students and the public by cards of admission. The promotion of physical culture will be a part of the regular collegiate course. Dr. E. Mussey Hartwell, who is in charge of this department, delivered an address on Physical Training in Colleges and Universities.

Medical and Surgical Journal.

THURSDAY, DECEMBER 27, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

ANNUS MEDICUS.

In looking back over the year 1883 one finds it not to have been an especially eventful year medically. As usual, a vast deal of medical literature has been printed, and, as usual, a very modest proportion thereof seems likely to be of permanent value. As usual, many new remedies have made their appearance, of which the majority will be weighed in the balance and found wanting. And yet the year has doubtless left the profession, on the whole, wiser than it found it. The eminent national societies, the American Surgical at Cincinnati, the Medical at Cleveland, the Neurological and Laryngological in New York, the Dermatological at Lake George, the Ophthalmological at Kaaterskill, the Gynecological at Philadelphia, the American Academy of Medicine in New York, have met and collected their observations, and countless less celebrated bodies throughout the land have doubtless borne good fruit in the truthful record of patient investigations. The fifty-first annual meeting of the British Medical Association, in August, at Liverpool, and the first annual meeting of the Intercolonial Medical Congress at Amsterdam, in September, deserve mention, as does the International Hygienic Exhibition held at Berlin during the summer, and postponed from last year on account of the destruction then of the building by fire.

Among the annual courses of lectures in England which have come to be looked to for the freshest and most authoritative presentation of medical knowledge on the subjects that they discuss, we have had during the past year the Gulstonian Lectures on Sterility in Woman, by Dr. J. Matthews Duncan; the Croonian Lectures on Modern Theories and Treatment of Phthisis, by Dr. James Edward Pollock; and the Lumleian Lectures on Uric Acid, its Physiology and its Relation to Renal Calculi and Gravel, by Dr. A. B. Garrod, all delivered before the Royal College of Physicians, London; the Lettsomian Lectures on the Treatment of Some Forms of Valvular Disease of the Heart, by Dr. A. E. Sansom, before the Medical Society of London; the Hunterian Oration before the Royal College of Surgeons of England, by Sir T. Spencer Wells. The Cartwright Lectures in New York were delivered by Dr. W. T. Belfield, of Chicago, On the Relations of Fungi to Disease.

A Collective Investigation of Disease has been organized under the auspices of the British Medical

Association, a movement from which some positive addition to our knowledge may reasonably be anticipated, and in which it is desirable that the American Medical Association and the State societies should coöperate.

The "irrepressible conflict" between Gaul and Teuton has appeared in the field of science in an acrimonious discussion, which began last year at the Geneva meeting of the International Congress of Hygiene, between the young pathologist of Berlin who gave us the tubercle bacillus and the old chemist of Paris who has been inoculating thousands of his countrymen's cattle against anthrax. Koch denies that the methods used by Pasteur in his culture experiments give sufficient guarantees that the microbes cultivated, attenuated, and introduced into new animals were simply and solely what Pasteur believed them to be. He went so far as to intimate that the inoculated animals in many cases died of a mere septicæmia. On the one ground of anthrax, where Pasteur's results seemed most impregnable, the German did not hesitate to assail him, somewhat rancorously it may be said, and claimed that a first inoculation with attenuated virus did not protect against the second and test-inoculation, nor against a subsequent spontaneous taking of the disease. Pasteur's reply and Koch's rejoinder, with their several successors, have occupied those medical journals given to polemics.

Later, Spina and Stricker, of Vienna, entered the lists against Koch, claiming that the bacilli which Koch considered peculiar to tuberculosis were indistinguishable from other bacilli which, when similarly treated, would take the same stain. Spina even went so far as to deny any infectious character whatever to phthisis, and altogether appeared to be quite a radical *microbioclast*.

The net results up to the present moment may be summed up as an increased confidence in Koch's methods of experimentation and investigation, and a consequent disposition to give his results respectful and careful consideration if not immediate acceptance. On the other hand, Pasteur's methods have been discredited, and a justifiable suspicion thrown upon his conclusions.

Both the German and French governments sent Commissions to Egypt to study cholera, Koch being at the head of the former, and accompanying it in person, whilst Pasteur assumed the direction of the latter, and was represented upon it by his young and accomplished assistant, M. Thuillier, who, as our necrology shows, fell a martyr to his scientific zeal at Alexandria. The Commissions each reported to its respective government. Each found a microbion, as bound in honor to do, but neither succeeded in proving its own discovery to be the cholera germ. The German micro-organism is a bacillus found principally in the walls of the lower part of the small intestine. The French micro-organism, as stated by M. Straus, of the Commission, was found in the blood, and is described as a very minute, elongated body, suggesting that of the acetic ferment or of pig cholera, though less elongated, and located in the clear spaces between

the blood globules. The determination of an acid reaction of the blood was also announced. The French Commission has returned home; the German, with the consent of its government, continued on to Bombay to follow up its investigations upon more ample material. Of its subsequent results nothing is known as yet.

During most of the earlier half of the year public attention was occupied by the attempts of his excellency, the Governor of this State, in a protracted series of legislative hearings, to impugn the management of the charitable institutions, and indirectly to expose the cause of medical education to popular odium by charging various indecencies and outrages in connection with the delivery and dissection of bodies of paupers. The majority of the committee reported that the Governor's charges were not established, and the shaft aimed at the Harvard Medical School over the Tewksbury almshouse fell harmless to the ground. Coincidentally (at least in point of time) with this agitation the new building of the School was injured by fire to the extent of several thousand dollars. The fire-proof character of the edifice restricted the damage chiefly to the internal finish, but a delay of some three months was necessitated for its restoration. The ceremonies on the occasion of the dedication and occupation of the building are fresh in the minds of all, as is also the vigorous defense then given by the Emeritus Professor of Anatomy of the conduct of the anatomical department in all its work during the many years he had had charge of it.

As in the previous year, New York has been the centre of Code controversy. In April the New York Academy adopted a resolution offered by Dr. Austin Flint, Jr., directing that none but supporters of the Old Code be eligible for the Academy. Reconsideration was moved by the Old Code men, and voted down with the view of "clinching" the position of the Academy. An adjournment under suspension of the By-Laws till October was made, when amendments offered by Dr. Barker, and designed to remove further discussions of this topic from the meetings of the Academy, failed of the two-thirds vote necessary to their passage. The New Code men, however, succeeded in carrying a motion rescinding the action of the Academy taken in the spring, so that the question is now, so far as that body is concerned, *in statu quo*. The New York delegates to the Cleveland meeting of the American Medical Association were not received on account of the attitude of the State Society on this question. No considerable gain has been made by either party to this dispute during the past year, and the question is one that threatens to continue to divert to itself time which could be spent much more profitably on scientific work.

To the Epidemiography of the year a good deal of interest attaches. At home our Southern border has been threatened at various points by yellow fever, a lodgment of which disease was happily averted everywhere except at the Navy Yard Reservation near Pensacola. The report of the Court of Inquiry convened by order of the Secretary of the Navy states

that the first case was observed August 3d, and suggests four possible sources of infection. A strict cordon was drawn around the infected district, and maintained until November 1st. The disease was confined to the Reservation and two small villages.

Yellow fever has been quite active in Havana the past summer. There were 152 deaths during the month of August, and eighty-six deaths during the month of October. Vera Cruz was also visited, and several towns along the Pacific coast and the Gulf of California, especially Guaymas, the termination of the Sonora branch of the Atchison Railroad, where the mortality was very large, continuing through the month of October. The type of the disease at this point exhibited some peculiarities.

The same good fortune or good management which has granted the United States an immunity from yellow fever has preserved the Continent of Europe from an invasion of cholera, notwithstanding the epidemic outbreaks in Egypt, in India, and China. The epidemic in Egypt was on an extensive scale, the number of deaths reported being between twenty-five and thirty thousand. The outbreak began at Damietta, a city of the Delta, the hygienic conditions of which were reported as exceptionally bad, even for an Oriental city. The disease spread rapidly throughout this town, and during the few weeks of its duration swept away about one fifteenth of the population. A cordon was established around the town after the disease had prevailed some time, but naturally without avail, and the epidemic spread rapidly to Cairo and the valley of the Nile above the capital.

The source of the outbreak at Damietta remains undecided, notwithstanding much discussion and many reports on the subject, but we need not on that account be driven into embracing a belief in a *de novo* origin. Equally fruitless seem to have been the somewhat warm discussions as to the value of quarantine against the disease. England continues to occupy one position on this question and the Continent another, and we must still revert to the Vienna Congress. No new and effective treatment of cholera has been brought to light that we are aware of.

GENERAL NECROLOGY.

Dr. George M. Beard, of New York, died on January 23d, at the age of forty-four. He devoted himself specially to nervous diseases, and was a voluminous and original writer.

Prof. Charles Sédillot, for many years Director of the Military Medical School of Strasbourg, died on January 25th.

Professor Von Sigmund, Professor of Syphilis in Vienna, died February 1st, in the seventy-fourth year of his age.

Prof. Carl Von Hecker died in his fifty-sixth year; he was Professor of Obstetrics in Munich.

Baron Jules Cloquet died on February 23d, at the advanced age of ninety-four. He was the author of several works on anatomy and surgery.

Prof. William Holme Van Buren, of New York, died March 25th, at the age of sixty-four. Professor

of Surgery at the Bellevue Hospital Medical School, he was best known perhaps as the author of a work on Diseases of the Rectum, and joint author with Dr. Keyes of a Treatise on Genito-Urinary Surgery. His work on the Sanitary Commission is a matter of public as well as of medical interest. To the great detriment of his private revenue he served his country faithfully upon this Commission and added largely to the efficiency of the sanitary conduct of the war.

Professor Von Bruns, of Tubingen, died in March. He was born in Brunswick in 1812, and was the author of several surgical treatises. His work on Laryngoscopic Surgery gained for him a grand prize of 20,000 marks offered by the Academy of Turin.

Dr. William Farr, C. B., died April 14th, at the age of seventy-five, to whom is due almost all our present knowledge of vital statistics.

Robert Druitt, M. D., F. R. C. S., author of the well-known Surgeon's Vade-Mecum, so long the surgical text-book of the Harvard and other medical schools, died on May 15th, aged sixty-nine.

Dr. Filippo Pacini, born at Pistoia, May 25, 1812, died at Florence, July 9th, at the age of seventy-one. He was perhaps the most distinguished and widely known of contemporary Italian physicians. Professor of Descriptive, Topographical, and Artistic Anatomy at Florence, and author of a large number of papers on a variety of subjects, his memory will be most generally associated with the discovery of the minute bodies known by his name.

Dr. A. P. Stewart, F. R. C. P., London, died in London July 28th, at the age of seventy. His name will be associated with a paper, published in the *Edinburgh Medical and Surgical Journal* in 1840, on The Differentiation of Typhoid from Typhus Fever. Dr. Stewart subsequently made some claims to priority in the statement of this differentiation, at least in England.

Professor Parrot died at Paris, August 5th, at the age of fifty-four. He was Professor of the History of Medicine at the Paris School, and chief physician to the National Hospital of the Legion of Honor. He made some important contributions to the pathology of children's diseases, indicated by the expression "Parrot's bumps."

Prof. N. A. Pedicino died at Naples in August, at the age of forty-four. He had already been six years Professor of Botany at the Sapienza, University of Rome. He was an advanced advocate of Darwinism.

Robert Boyd, M. D., F. R. C. P., London, etc., etc., died August 14th, at the age of seventy. He lost his life, as did one of his sons, whilst striving to save patients from the flames of his private lunatic hospital. His end was gallant as his life had been useful. He was the author of many important papers relating to his branch of medicine, among which that on the Weight of the Brain at Different Ages and in Various Diseases is probably the most widely known.

Henry J. H. Bond, M. D., died in September, at the age of eighty-two. He was formerly Regius Professor of Physic at Cambridge, England.

Louis Thuillier, M. D., died of cholera at Alexan-

dria on September 18th, at the age of twenty-seven. He was the assistant of Monsieur Pasteur in his laboratory at Paris, where he took an important part in the researches upon *charbon*, *rouget* of pigs, and the so-called typhoid fever of horses. He went to Egypt at Pasteur's request as a member of the French Commission to Investigate Cholera, and died one of the last victims to the disease at Alexandria.

Dr. James A. Sewell, of Quebec, aged seventy-three, Dean of the Medical Faculty of Laval University, died on October 2d.

Charles H. Crane, Surgeon-General U. S. A., died October 10th, in Washington, aged fifty-eight, after a brief service as surgeon-general of one year and two months.

Francesco Cortese died October 25th, at Rome, aged eighty-two. He was formerly Surgeon General of the Sardinian army.

Prof. J. A. H. Depaul died at Paris in October, at the age of seventy-two. A distinguished obstetrician, and at one time President of the Académie de Médecine, he was the author of a treatise on Obstetrical Auscultation.

James Shuter, M. B., F. R. C. S., died November 1st in London, aged thirty-seven. He was Assistant Surgeon to the Royal Free Hospital and to St. Bartholomew's Hospital. Mr. Shuter was a careful and accomplished surgeon who had particularly endeared himself to his associates and his students, to whom he devoted much time and labor. He died from an overdose of morphia. While taking a hypodermic injection the vial containing the morphia solution was broken and the solution poured into a glass resembling one that contained a saline mixture. These mixtures were alike in color and quantity. It was supposed that while semi-unconscious Mr. Shuter reached from his bed, took up the wrong glass, and drank the morphia solution.

John Macnaught, of Liverpool, died November 3d, at the age of ninety years. Though for a few years retired from practice, he had continued in actual practice for sixty-five years. He took his degree of M. D. in 1815.

Dr. J. Marion Sims died at New York November 13th, at the age of seventy-one. His name is identified with the speculum which he invented, with the use of silver wire sutures, and with the treatment of vesico-vaginal fistulæ. The first account of his operation for fistulæ was published in January, 1852. He was President of the American Medical Association in 1876, and founder of the New York Hospital for Women.

Charles Hilton Fagge, F. R. C. P., died in London on November 15th, aged forty-five, of aneurism of the aorta. Physician to Guy's Hospital, he also held appointments at different times as Lecturer in Hygiene, Physics, and Materia Medica. He was the editor and translator for the New Sydenham Society of Hebra's *Exanthemata and Diseases of the Skin*, and was the author of numerous articles, among which may be mentioned those on Intestinal Obstruction and The Murmurs attendant on Mitral Contraction, in Guy's Hospital Reports of 1869 and 1871. He also studied

deeply and wrote somewhat extensively upon physiological tests as a means of detecting poisons.

Prof. G. B. Ercolani died November 16th, at Bologna, at the age of sixty-four years. Of an ancient and noble family, he developed an early and deep interest in comparative anatomy and pathology. During the events of 1849 he was a strong liberal in politics. Most of his publications have appeared in the *Memoirs of the Academy of Bologna*. His great work on the *Histology and Physiology of the Placenta of Mammals* was rendered into English by Dr. H. O. Marcy.

Dr. Thomas Story Kirkbride, M. D., Superintendent of the Pennsylvania Hospital for the Insane, died in Philadelphia, December 17th, at the age of seventy-four. Dr. Kirkbride's name has been associated with the study of insanity for over fifty years, and he has been at the head of the insane department of the Pennsylvania Hospital since 1840. He was one of the founders and for eight years President of the Association of the Medical Superintendents of America.

NECROLOGY OF MASSACHUSETTS MEDICAL SOCIETY.

The following members of the Massachusetts Medical Society have died during the year. For the list we are indebted to the kindness of Dr. F. W. Goss, the Secretary of the Society:—

January 16th, Walter Burnham, of Lowell, aged seventy-five.

February 22d, Joseph Nye Bates, of Worcester, aged seventy-two.

February 25th, Jeremiah Joseph McCarthy, of Charlestown, aged thirty-five.

March 1st, William Marshall Parker, of Milford, aged fifty-four.

April 11th, Daniel Holt, of Lowell, aged seventy-three.

April 26th, Clement Adams Walker, of Boston, aged sixty-two.

May 2d, James Otis Parker, of Shirley, aged seventy-one.

May 10th, Edward Julius Sawyer, of Gardner, aged fifty-three.

May 15th, William Henry Prince, of Newton, aged sixty-seven.

May 25th, Daniel Thompson, of Northampton, aged eighty-three.

June 26th, Jefferson Pratt, of Hopkinton, aged eighty.

June 28th, Edward Mead, of Roxbury, aged sixty-four.

July 8th, Erastus Otis Phinney, of Melrose, aged seventy-three.

August 19th, George Grenville Tucker, of Westfield, aged forty-nine.

August 23d, Horace Poole Wakefield, of Leicester, aged seventy-four.

September 30th, James Aloysius Fleming, of Boston, aged thirty.

October 3d, George Jerome Arnold, of Roxbury, aged forty-eight.

October 20th, Samuel Eaton Fitz, of Roxbury, aged forty-seven.

October 23d, Robert Dwyer Joyce, of Boston.

October 29th, Alba Enoch Kemp, of East Douglas, aged sixty-one.

November 7th, Joseph Allen Fay, of Milford, aged thirty-nine.

November 12th, Marshall Spring Mead, of Northfield, aged eighty-one.

November 15th, Simeon Parker Dresser, of Hinsdale, aged thirty-eight.

December 8th, Friend Drake Lord, of Newton Lower Falls, aged sixty-two.

December 14th, Calvin Ellis, of Boston, aged fifty-seven.

MEDICAL NOTES.

— It appears that the suggestion of General Howard to "brand" deserters, which has excited so much indignation on the part of the public press, was totally misapprehended. The recommendation actually made was that after a first offense a distinctive mark should be tattooed (not branded) into the skin at some part covered with clothing so that the offender should not be allowed to reënlist.

— The position of surgeon-general on the staff of Governor Robinson was tendered, it is understood, to Hon. Samuel A. Green, M. D., of Boston, who declined the honor on account of professional and personal engagements, and because of his intention to spend a considerable portion of next year abroad. Dr. Alfred F. Holt, of Cambridge, has been appointed to the position.

— At a recent meeting of the Pathological Society of New York a specimen was exhibited by Dr. B. Robinson consisting of a heart from an individual six feet four inches tall, and of corresponding proportions, who had suffered for years from symptoms of disturbed circulation. The organ weighed fifty-five ounces, and was believed by Dr. Robinson to be the largest on record. The president, however, cited one formerly presented to the Society by Dr. Clark, which weighed fifty-seven ounces.

— We find the following interesting bit of pathology among the suburban items of a daily contemporary: "The death by pneumonia of an infant child of Richard Sanderson was caused by a raw bean which the child had swallowed, and which sprouted in the stomach."

— An attack has been made in the columns of the *Standard* newspaper of London on Drs. Ringer and Murrell for illegal experimentation on patients by means of sodium nitrite. The facts on which the charge was made were obtained from the publication of results by the gentlemen themselves. While it is, perhaps, not to be wondered at that the lay press should misinterpret such experimentation, it is cause for surprise and regret that such an attack should receive any aid from the medical profession either by individuals or the professional press. The *Medical Times and Gazette* has editorially condemned these gentlemen for researches of a character necessary to be made before valuable scientific progress in therapeutics can be secured.

— Garcia (*London Medical Record*, October 15th) recommends a useful modification of Boyer's method for the reduction of paraphimosis. He begins by applying over the whole member, from vertex to base, a spiral bandage, narrow and wet with cold water, the patient being told to continually pour a stream of cold water over the affected part. After five minutes the bandage is taken off and replaced rapidly by another in the same manner, but tighter; the irrigation is continued. After five more minutes the second bandage is taken off, and a third is applied still more tightly. After a little time we may proceed to the reduction by the ordinary method, seizing the member with the index and middle finger of each hand, and pushing the glans with both thumbs. Reduction is generally easy. The number of times that the bandage must be applied depends naturally on the amount of tumefaction and the effect obtained by each application.

— Professor Von Ziemssen employs distention of the large intestine by carbonic acid gas as a means both of diagnosis and of treatment (*Wien. med. Blätter*, July 19th). His method of introducing the gas is by passing into the intestine, through a tube about six inches long, about 300 grains of bicarbonate of soda and 270 grains of tartaric acid, which is sufficient to produce ten pints of gas. The distention serves to indicate the form and position of the intestine, with its relations to neighboring organs and the condition of its valves. It is said to be therapeutically useful to excite peristaltic action, when a somewhat smaller amount may be used, and for relieving malposition and obstruction. It is more efficient and less harmful than distention by means of water or other fluid, and although the breaking down of adhesions may cause pain inflammation does not follow. The only cases in which it is contra-indicated are enteric fever and intestinal tuberculosis.

— The new edition of *The Medical Register for New England*, by Dr. Francis H. Brown, soon to be issued by Cupples, Upham & Co., will contain much new data and information on medical matters, carefully compiled by the author. The work has grown to such importance that no physician or surgeon in the country should be without it, containing as it does more information respecting the medical profession than any other manual in the market.

— The *London Medical News* is responsible for the following:—

"SURGICAL CUTENESS. An instance of surgical 'cuteness' is just recorded from Paris, the subjects of which are those miserable creatures, as stupid as they are ugly, yclept poodles. It has occurred to a veterinarian that by a slight modification of nature's arrangement the poodle's tail can be converted into a convenient handle, wherewith the animal may, as occasion requires, be lifted from place to place. He shaves the dog neatly, scarifies the tip of its tail, makes an incision for the reception of the tip beneath the skin of the animal's back a little behind the fore shoulder by means of a transverse cut, then, lifting the dermic tissues with the handle of the scalpel until a sufficient excavation is

made, he inserts the tip of the tail in the wound and securely bandages it there. The result is a teapot sort of production that is eminently suggestive of the necessity for an appointment on the part of the Society for the Prevention of Cruelty to Animals."

— Among the perils to which man is subject by his environment we now have that of flies, and light is thrown upon the noxiousness of one of the plagues of Egypt, to which the race has been unconsciously exposed ever since the days of Pharaoh. Dr. Grassi has published in the *Gazzetta degli Ospitali* for July 25th the results of some observations in which he discovered unchanged in the feces of flies the eggs of various kinds of worms, including the tape-worm, the thread-worm, and the whip-worm, the flies having been fed on food containing these delicacies. Fly-blown meat is thus a source of infection. The fly-trap must be added to the antiseptic armamentarium.

— It is said in the New York correspondence of a daily contemporary that Van Marck, the famous cattle painter, has the painter's cramp so badly as to be unable to wield the brush with his right hand. He has been idle for the last few months, and will begin to work with his other hand if he does not soon recover. According to the same authority some of our Americans—Wynant and F. E. Church among them—paint entirely with their left hands.

— The "Medical Venus" was, according to Mr. Anthony Trollope, in his autobiography, the object of anxious inquiry on the part of an individual whom he met in some of the art galleries of Europe. This person finally found the aim of his search at the Uffizi Palace at Florence under the better-known title of the Venus de Medici. Whether it was the anatomical perfections or the surgical deficiencies of this celebrated statue which suggested the new title we are not informed. The name, however, presents for our sisters in the profession a new tutelar divinity possessing certain advantages over the god who for so many centuries has stood as the poetic representative of the healing art. Now the unfortunate limitations in the symbolism of Apollo may be remedied by a transfer of worship on the part of the female practitioners to the Medical Venus.

NEW YORK.

— The Hudson County Grand Jury has made a presentment respecting the pollution of the Passaic River by the sewers and factory refuse of the city of Newark, and recommends that the Newark authorities should construct an intercepting sewer which shall carry the sewage into Newark Bay, and thus prevent the danger which now threatens the health of the people of Jersey City and Bayonne from the contamination of their water supply.

— Dr. E. W. Martin, one of the milk inspectors in the service of the State Board of Health, recently found that a firm at Chester, New York, which manufactures an immense quantity of "Neufchâtel" cheese for sale in New York City, were using skimmed milk, and supplying the fatty matter, lost by removing the cream, with lard; emulsifying machines being used for

blending the latter with the skimmed milk. On receiving his report the State Board of Health referred the matter to the local health board, which, at a meeting held December 10th, appointed a committee to procure the indictment of the firm by the next Grand Jury.

— The Aqueduct Commission have adopted for the new aqueduct the route known as the modified line of the Hudson River route, which passes through the Pocantico and Saw-mill River valleys, some distance back from the Hudson, to a point near South Yonkers, where it is intersected by the line of the Hudson River route, which it follows to the Harlem River.

— A meeting in behalf of the Charity Organization was held at the hall of the Union League Club on the 5th of December, at which addresses were made by Messrs. Parke Godwin, Joseph H. Choate, and George William Curtis, Chief Justice Daly, and the Rev. Dr. Rylance, while the Rev. Theodore Williams explained the working of the system of charity organization in Boston.

— At a meeting of the Academy of Medicine held December 20th, Dr. Charles Heitzman made a report on the progress of biology in Europe, which was principally devoted to the state of opinion in regard to his own peculiar views which he found during a recent trip abroad. These views were enunciated in 1872 and 1873, and as it required an unusually well-trained eye and exceptionally good lenses to discover the appearances which he described, he said he was not surprised to find that the scientific world was slow about adopting his theory of tissue structure. One of the first claims that he had made was in regard to protoplasm, which had always been supposed to be structureless, but which he discovered to have a well-marked reticulum; the net-work building up the nucleus and the nucleoli consisting of living matter. This view was now adopted by many of the best authorities in Europe, although there were some exceptions. Beale had claimed that the nucleus alone consisted of germinal matter; but he contended that the nucleus was simply the reticulum in more compact form. Contrary to the views of the advocates of the cell doctrine, he believed that the basis or intermediate structure was not destitute of life, but endowed with the same life as the ensheathed elements. On this was based a new view of the structure of the whole body. He stated that Stricker, after six years of labor, had definitely acknowledged that his theory of the constitution of basis structure was correct. In the cornea of a frog in a state of slight inflammation he had distinctly observed that the basis structure was composed of a mass of filaments in undulating motion. Stricker in the last volume of his Pathology had given him full credit for all his discoveries, and admitted that there was no difference, as regards life and the power of reproduction, between the reticulum and the cells proper; while Spiena, of Prague, had announced in his latest publication, as the result of his investigations, that the time had now come when the old cell doctrine must be given up. Both Stricker and himself, as well as other observers, now denied entirely that there were any wandering corpuscles, as

first claimed by Cohnheim, and if they were right, the whole pathology of inflammation would have to be changed. He then went on to speak of the structure of epithelial tissue, which in 1873 he had claimed to be distinctly reticular, and in regard to which some of the best observers in Europe now coincided with him. Finally, he argued against the conclusions of Koch on the subject of tuberculosis, and said that he was fully in accord with Stricker and his followers, who held that the bacillus was simply a product, and not the cause, of tuberculosis. For a number of years he had taught that tuberculosis was a strictly constitutional disease, which occurred only when there was already a lack of living matter in the system for the reproduction of blood corpuscles. His opinions on this subject were based on the observations which he had made in three hundred post-mortem examinations of those dying with tuberculosis.

Dr. William H. Welsh, Professor of Pathological Anatomy and General Pathology in Bellevue Hospital Medical College, made some remarks upon Dr. Heitzman's address, in which he took up the subjects treated upon in succession, and stated that he could not agree with him upon any prominent point. Heitzman and Stricker stood almost alone in their peculiar opinions, and he thought that for the present, at least, the matter must be left *sub judice*.

— The Hospital Saturday and Sunday Association has published its annual statement and appeal. The hospitals which are represented in the Association, and which are to receive the benefit of the December collection (with the exception of the Roosevelt and New York Hospitals, which waive their claim to a share of the undesignated contributions this year) are as follows: nine general hospitals; four hospitals for diseases of women or children, or both; two hospitals for the ruptured and the crippled; four hospitals for diseases of the eye, ear, or throat, or all combined; three hospitals for incurables; and the New York Skin and Cancer Hospital. In the statement is given a synopsis of the work and resources of each of these institutions, including the total expenses, the amount expended during the year on enlargement and improvements, the amount expended in the care of patients, the total income from invested funds, the amount received from paying patients, the amount received from city, county, or State appropriations, the amount received from contributions not made to the permanent fund, the receipts applicable to current expenses, the total number of patients treated, the number of free patients, the total number of days of hospital care, the number of days of hospital care for free patients, the average cost per patient, and the average cost per day per capita. In three different hospitals 10,442 patients were treated during the year ending September 30th, and of these 7533 were free patients. With the city's growth there is a steady increase of work on the part of the hospitals, while, on the other hand, the regular incomes of many of them are considerably reduced because invested funds which formerly paid five, six, or seven per cent. interest are now returning only three, four, or five per cent.

Under these circumstances it is trusted that the public will make a liberal response to the appeal of the Association. The collection will be made on Saturday and Sunday, December 29th and 30th.

—The new east wing of the City Asylum for the Insane on Ward's Island, which was recently completed at a cost of \$100,000, was damaged by fire to the extent of \$20,000 on the morning of December 21st, but, fortunately, no patient or employee was injured or killed. There were ninety patients in this wing, of whom no less than fifty-nine were bed-ridden, and altogether 497 patients were removed from the wings east of the central building to the wards in the western wings of the hospital. There was no panic, and great credit is due to Dr. Macdonald, the superintendent, and his assistants for the manner in which they were transferred. Great complaint was made of the inadequacy of the provision on Ward's Island for the extinguishing of fires breaking out in the public institutions situated there, and it was merely a matter of good fortune that the present conflagration was not more disastrous in its character and consequences. In February last the chief of the Fire Department called special attention to the very defective arrangements on the island, but nothing was ever done to remedy the evil.

—At its last meeting the Board of Aldermen passed an ordinance making it compulsory on the part of the electric light companies to place their wires below the surface of the ground within two years from the present time. During the discussion of the measure a communication was read from the Board of Health in which it was stated that in the last three years there had been one death in the city by shock from an electric current, and two deaths of employees from other accidental causes. It is said to be a fact that thus far no satisfactory system of underground wires has yet been devised, but the period of two years specified in the ordinance will allow the companies sufficient time to solve the problem.

PHILADELPHIA.

—The health of this city seems to be unusually good, and if it were not for occasional suicides and accidents the undertakers would be in danger of finding their occupation gone. The doctors are now largely engaged in brushing up their acquaintance with the classics, investigating bacilli, or talking politics, according to the bent of their minds.

—The commission appointed by the Governor of the State to inquire into the mental condition of a murderer named McGinnis, now lying under sentence of death in the County Prison (who shot both his wife and mother-in-law, the former recovering, the latter not), has just made its report. Of the five members of the commission Drs. Thomas G. Morton, Charles K. Mills, S. Preston Jones, William P. Moon, and Thomas H. Andrews, all except Dr. Morton declared the man to be insane, his principal delusion being with regard to his wife's unfaithfulness, but also having hallucinations and illusions of sight and hearing, the victim of delusional monomania. Dr. Morton

dissented from the majority report, and declared the man sound in mind and body. The charges against his wife constituted, in his mind, part of his systematic brutality to her, and having some foundation in rumor; the fact that it was nothing but a delusion not having been established by evidence. Strange to say both the majority and minority reports agree in their recommendation of imprisonment for life; the former on the ground that Pennsylvania has no insane asylum secure enough to keep such insane criminals, the latter in order to demonstrate the truth of the proposition that the man is sane, and because of scruples against capital punishment.

—Professor Da Costa has had some very satisfactory results from the treatment of dyspnoea by quercin. In a recent lecture he said that in his experience it had been especially serviceable in two classes of cases: (1) in purely nervous asthma he had found it to be invaluable; (2) in cases which have been rather loosely called cardiac asthma, cases in which a heart lesion has produced failure of cardiac contraction and consequent congestion of the lungs, he had also known it to be very useful. It may serve as a cardiac tonic or may do good solely by its action upon the respiratory centre in the medulla. Whatever may be the explanation, however, it gives wonderful relief in appropriate cases. The way in which he gives it is the fluid extract in doses of twenty minims every hour, gradually increasing the amount, some patients requiring as much as a drachm before relief is obtained. The good effects are observed usually after two or three doses have been taken. The taste is well covered by using equal quantities of the French syrup of red orange and water as the vehicle. In this form it usually agrees with the stomach. As the respiratory symptoms are relieved the remedy may be given at longer intervals.

—Commenting recently upon a case of myelitis, Da Costa spoke of an old history of syphilitic infection, and pointed out the fact that the spinal disease was not necessarily syphilitic because the patient had at one time had a chancre. Referring to the prevalent error of attributing all the subsequent events of life to syphilis, he declared that if this man were to cut his throat some would be ready to regard it as a syphilitic manifestation.

—Dr. R. J. Levis recently operated upon an unusual case at the Pennsylvania Hospital. A man, forty-three years of age, gave a history of difficulty in defecation, in its origin dating back some three years. Of late he had been obliged to resort to purgatives and enemata in order to secure evacuation. Hardened faeces were sometimes the cause of some bleeding from the rectum. Two years ago he suffered with an inflammatory trouble in the perineal region, and with retention of urine. One year ago he detected a small tumor within the rectum by the introduction of his finger to relieve the tenesmus. It was then the size of a walnut. This tumor, when he came under observation, had attained the size of a foetal head. By an effort the mass could be made to appear outside the sphincter ani. Upon examination the growth

was found to be beneath the mucous membrane of the bowel, having its origin in the submucous structures of the bowel to which it was attached or in the connective tissue. Dr. Levis grasped the tumor with strong hooks, and pulled it downward, and easily enucleated it. After removal it was found to be rather dense and elastic; it was nearly three inches in diameter, and weighed twenty-four ounces. It was pronounced a spindle-cell sarcoma upon microscopic examination, making it one of the rarest growths in this situation.

Correspondence.

HOSPITAL DUTY, PAST AND PRESENT.

MR. EDITOR.—It will, I hope, be allowed one of the medical elders to intrude himself upon your valuable columns, and venture a few remarks comparing the present with the past, in regard to the performance of hospital duty. In my active days a hospital or dispensary service was considered a position of honor, but of honor to be purchased by hard work. For twenty-five years of my hospital service I think I absented myself but one week, and then my non-attendance was occasioned by severe sickness in my family. I may add that so far from diminishing, my interest grew each year, and had not abated when my failing strength obliged me to offer my resignation, which my colleagues were kind enough to say they accepted with regret. At the present time, however, I hear not only of hospital and dispensary men who frequently absent themselves during their service, but of some who make this an habitual practice, and of others who, while holding a position for years, have never completed a single term of service in full. I do not wish to be regarded as considering that as close application as I happen to have practiced is necessary or even advisable, for certainly a vacation, especially in summer, or a few months of travel for those who can enjoy the opportunity "*donec canities abest morosa*," is desirable, and after years of faithful labor it is right for trusted servants to be allowed an occasional rest. This, however, is entirely different from the conduct of these physicians who have not been long in service, and yet who habitually enjoy their *otium sine dignitate*, leaving to young and inexperienced men the routine work, while they claim the honor of their positions. In how many banks would it be permitted to a cashier to habitually absent himself while a clerk performed his duties? and are not hospital and dispensary positions also positions of trust? Yours very truly,

NESTOR.

VOLUNTARY DISLOCATION OF THE HIP-JOINT.

STERLING, WELD COUNTY, COL., December 10, 1883.

MR. EDITOR,—The following case, falling under my observation, may be worthy a place in your "Medical Notes," for, so far as I know, no similar one in which advantage is gained from the condition involved has been mentioned:—

The patient, a telegraph operator, forty years of age, has, since childhood, been able to dislocate the right hip by a muscular effort at will. After sitting for a

time in the usual posture he throws the head of the femur on to the dorsum ilii, inclines slightly to the right side, and brings the weight of the body to bear on an almost entirely new surface, and when fatigued a second muscular effort replaces it, and he resumes the usual upright position. A well-marked sound accompanies the displacement from the acetabulum. Other joints are normal, although the ligaments of the thumbs are relaxed.

Yours, etc., J. N. HALL, M. D. (Harv.).

THE APPROPRIATION TO PREVENT THE SPREAD OF EPIDEMIC DISEASE.

{ U. S. MARINE HOSPITAL SERVICE, OFFICE OF THE SURGEON-GENERAL, December 22, 1883.

MR. EDITOR,—In your issue of December 20th a correspondent, N****, in attempting to correct what he terms a "false impression" said to be created by your review of the report of the United States Marine Hospital Service for 1883, has fallen into an error. The appropriation for "Preventing the Spread of Epidemic Diseases," being for a specific purpose, does not lapse at the end of a fiscal year. For the benefit of your correspondent, as well as others who may have been misled by his criticism, it may be well to state that there have been two appropriations of \$100,000 each for the fiscal year ended June 30, 1883, and the present year, ending June 30, 1884. The expenses incurred by the United States Marine Hospital Service for the past two fiscal years have been as follows:—

For the fiscal year ended June 30, 1883, \$54,678.10, and for the quarantine season ended November 1st, last, \$39,468.88, a total of \$94,146.98. It will thus be seen that the total expense for the two years has not yet absorbed the first \$100,000 appropriated by Congress, and the second \$100,000, appropriated for the present fiscal year, yet remains in the treasury untouched.

Very respectfully,

CHARLES E. BANKS, P. A. Surgeon, M. H. S.

Miscellany.

EPIDEMIC PNEUMONIA.

We find in the *Medical Press and Circular*, November 21st, an account of a somewhat remarkable epidemic of pneumonia which occurred in Tregnano (Verona) in the months of March and April of the present year. It is furnished by Dr. Roberto Massalongo, of Verona, who published the account in the *Gazetta Med. Ital.*, in July and August.

The scene of the outbreak, from its isolated situation, rendered the observations peculiarly interesting and valuable. Tregnano lies in a rather narrow valley, and contains about 2000 inhabitants. They are spoken of as of a healthy constitution, and as having never been subjected to any epidemic sickness before the one under notice. No peculiar meteorological phenomena were observed previous to the outbreak. The disease first began as an epidemic, that is, as attacking numerous individuals in rapid succession, in a circumscribed portion of the town, hard by a pond in which washing was carried on. The bottom of the pond was in consequence covered with a layer of mud, the water was of a green color and had a disagreeable odor. In

the whole about one hundred persons were attacked. The mortality reached about thirty per cent. All ages were alike affected, but the proportion of cases occurring among males, as compared with females, was about four to one. The first cases were observed in a cluster of houses standing in close proximity to each other, and in each of these two, three, four, and even five individuals were attacked. From these houses as a starting point the disease advanced from door to door, gradually encroaching upon the neighboring localities, until the whole town was subject to it. Those first taken were children, then followed those of middle age, and last of all the old people. No instance was observed in which the attack was preceded by a "cold." The various members of a household were not attacked simultaneously, but in succession; the one in attendance on the sick was usually the one to give way. Prodromal symptoms generally preceded the onset by some days; these were a feeling of malaise, loss of appetite, headache, etc.; in no instance was a rigor observed. Delirium and stupor gave the disease very much the appearance of typhus. The temperature was never observed to be higher than 40.7°C ., and its course was not so regular as usual. In some cases, during the whole febrile period, no localization was ascertainable in the lungs, but in all the others it was after one or two days, never on the first. Simultaneously with the appearance of local symptoms, in the majority of cases, the spleen was also observed to enlarge, very frequently also the liver, and sometimes at the height of the disease there was in addition to the above enlargement of the heart. Principally, and at first, the upper portions of the lungs were attacked, and after them the lower; in the great majority of cases both lungs were affected and almost always simultaneously. A simultaneous pleuritic effusion was only observed in four cases. The stage of hepatization lasted usually from seven to nine days, never less than five, and in one third of the cases it lasted more than twelve. Herpes labialis was observed in four cases only. The urine almost invariably contained albumen, the quantity increasing during the usually protracted period of resolution. Many cases were complicated by symptoms of meningitis and articular inflammations in one or more joints. Convalescence was very irregular, very protracted, the patients were very low, suffered from constipation with painful stools, want of appetite, nausea, sleeplessness, vague muscular pains, palpitation on the slightest exertion, the pulse weak, rarely as high as 50. It was remarked that three of the individuals attacked were suffering from phthisis, but none of them had previously suffered from pneumonia. Only two persons suffered relapses. The disease ran a chronic course in one case. In those cases in which the disease proved fatal, in the majority of cases the fatal termination came on in the period of commencing resolution, very rarely at the height of the disorder. In two cases it occurred suddenly during convalescence. After death putrefactive changes came on with striking rapidity. The period of incubation lasted from three to, at most, six days. The treatment consisted mainly in the exhibition of stimulants, antipyretics were but little employed, and with but little effect. Ice bags were, however, more useful. In the sputa, by means of the Weigert-Koch method, the author was able to determine the presence of micro-organisms, which perfectly resembled those described by Klebs, and which are supposed to be characteristic

of pneumonia; their number was greatest in the advanced stages of resolution.

COLORADO CLIMATE FOR CONSUMPTIVES.

Science for September 28 and October 5, 1883, contains a paper by Dr. Samuel A. Fisk, of Denver, Col., on the climatic advantages of Colorado in the arrest and cure of phthisis. The basis of the article is a series of tables collated from the observations of the United States Signal Service, giving a comparative view of various localities with reference to elevation, precipitation, and other elements. The places selected are Augusta, Ga. (the nearest available spot to Aiken, S. C.), Jacksonville, Fla., Boston, Newport, R. I., New York, Philadelphia, Chicago, St. Paul, Denver, Santa Fé, Salt Lake, and Los Angeles, Cal., representing a wide range of locality, and including several resorts especially frequented by consumptives.

The writer first considers the item of high elevation, and discusses its effect on the circulation and respiration as well as the advantages it affords in free ozone, an aseptic atmosphere and observed immunity from the disease on the part of its inhabitants. Denver is 5294 feet above the sea (the highest of any of the places considered except Santa Fé). The extra work put upon the heart by high altitudes is acknowledged, as well as the risks to which it exposes patients with organic cardiac affections. At the height of 5000 feet the heart-beat accelerates by ten strokes per minute, or 14,400 per day. The rapidity of circulation varying directly with the pulse rate and inversely with the atmospheric pressure, the number of circulations of the blood is estimated to be increased nearly 30,000 per day. This increases both the rate of waste and of repair in the body. Pneumonias run a shorter course. The expectoration of consumptives is increased in amount. This may act favorably in early cases by removing the morbid products, but in late cases it would naturally aid in the breaking down of lung tissue. Moreover, increased activity of circulation means increased metamorphosis of tissue, and hence an augmented appetite.

The effect of high altitudes on respiration is to increase the rate as well as the depth of the inspirations. This may be due to diminished atmospheric pressure, which by lessening the resistance to the inspiratory muscles increases their effectiveness. The author doubts the explanation often given for increased respiratory rate at high elevations, namely, that there is a paucity of oxygen, and hence more air must be taken in. He gives figures which seem to show that there is a great excess of oxygen over the requirement of the lungs in each cubic foot of air inspired even at high altitudes, so that there can be nothing like an "oxygen starvation." But, on the other hand, it might be claimed that the diminution of oxygen, while not sufficient to equalize the tension of that gas in the air vesicles and in the blood, is yet sufficient to make that difference in tension less than at lower levels, and so make the osmosis less free than it would be at a lower height, so that the economy might have more difficulty in obtaining its required oxygen. This, however, is a theoretical point. Practically we know that with fuller and more frequent respirations the extreme portions of the lungs, more especially the apices, where morbid processes are apt to begin, are brought into

activity, and hence a beneficial effect is produced. Other tables show a mean humidity of 45.8° at Denver as compared with 68.5° at Boston, and 69° at Jacksonville; an annual precipitation of 14.77 inches as compared with forty-nine inches at Augusta, and fifty-five at Jacksonville.

The wind prevalent at Denver is south, which is the favorable wind for invalids, while the prevalent wind at Los Angeles, west, and that at Augusta and Jacksonville, east, are the unfavorable winds. In regard to the number of clear, fair, and cloudy days, the author says that "in Denver there is only about one eighth of the entire year when an invalid would be kept in the house on account of the weather; in Jacksonville and Augusta he would be confined to the house for the same reason one quarter of the year; in St. Paul he would be kept in-doors between a third and a quarter of the time; while in Boston he would have to be housed a good third of the time."

In conclusion we can only say, by way of criticism, that most of the points the author makes in favor of Denver seem, from the tables, to be still more favorable to New Mexico. And it has been objected by advocates of Aiken that Augusta, though the nearest signal station, is by no means representative of the climate of the former place. The tables certainly, as far as they go, have a permanent value, and the con-

clusions drawn seem for the most part legitimate and quite suggestive.

TRACTION SUTURES.

DR. OSCAR H. ALLIS writes in the *Annals of Anatomy* (September, 1883), regarding the treatment of cases where so large a portion of integument has been cut away — as in removal of the female breast — that the healthy borders cannot be fully approximated, and in which even an attempt to do so is accompanied with such a degree of tension that the sutures soon cut their way out. To distribute this tension he employs a device which he thus describes:—

"After drying the skin thoroughly, I apply strips of adhesive plaster from the margin of the wound in the direction I wish the sutures to hold. I then pass my needle deeply through plaster and skin. After the sutures are in position, and before tightening them, I request an assistant to approximate the margins of the wound by pressure from his hands, while I secure them by twisting the wire.

"Sutures employed in this manner have a firm hold upon the plaster, exert their traction upon a large surface, are less irritating and harmful, and will continue an efficient action much longer than the ordinary integument sutures."

REPORTED MORTALITY FOR THE WEEK ENDING DECEMBER 15, 1883.

Deaths reported 3722: under five years of age, 944: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 536, consumption 418, lung diseases 378, diphtheria and croup 218, scarlet fever 85, typhoid fever 62, diarrhoeal diseases 51, measles 37, malarial fevers 33, whooping-cough 16, puerperal fever 12, erysipelas 10, cerebro-spinal meningitis 11, small-pox six. From *diarrhoeal diseases*, New York and New Orleans nine each. From *measles*, District of Columbia 12, New York 11, Brooklyn three, Baltimore two, Chicago, St. Louis, and Worcester one each. From *malarial fevers*, New Orleans eight, St. Louis seven, New York and Brooklyn six each, Baltimore four, Chicago one. From *whooping-cough*, New York six, Baltimore three, District of Columbia two, Philadelphia, Chicago, St. Louis, Milwaukee, and New Haven one each. From *puerperal fever*, Boston five, New Orleans and Buffalo two each, New York, District of Columbia, Lowell, and Fitchburg one each. From *erysipelas*, New York three, Philadelphia two, Brooklyn, Boston, St. Louis, Baltimore, and Worcester one each. From *cerebro-spinal meningitis*, Philadelphia, Chicago, and Buffalo two each, New York, Boston, Cincinnati, Milwaukee, and Brockton one each. From *small-pox*, New Orleans four, Philadelphia two.

Six cases of small-pox were reported in St. Louis; scarlet fever 47, diphtheria 44, and typhoid fever 14 in Boston; scarlet fever 15, and diphtheria five in Milwaukee.

In 77 cities and towns of Massachusetts, with an estimated population of 1,208,483 (estimated population of the State

1,922,530), the total death-rate for the week was 21.60 against 19.52 and 16.56 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending December 1st, the death-rate was 23. Deaths reported 3792: acute diseases of the respiratory organs (London) 453, scarlet fever 137, measles 98, fever 76, whooping-cough 66, diarrhoeal diseases 42, diphtheria 33, small-pox (London and Birmingham five each, Sunderland three, Liverpool and Newcastle one each) 15. The death-rates ranged from 16.3 in Bedford to 29.4 in Manchester; Birkenhead 18.2; London 21.8; Bristol 22.1; Sheffield 22.6; Birmingham 23.5; Nottingham 24.1; Leicester 24.2; Leeds 26; Liverpool 26.6; Newcastle-on-Tyne 29.3. In Edinburgh 19.7; Glasgow 26.3; Dublin 25.7.

For the week ending November 24th, in German cities and towns, with an estimated population of 8,749,864, the death-rate was 23.8. Deaths reported 3999; under five years of age, 1769; consumption 537, lung diseases 446, diphtheria and croup 286, diarrhoeal diseases 130, scarlet fever 92, measles and röteln 72, typhoid fever 69, whooping-cough 68, puerperal fever 19. The death-rates ranged from 12.8 in Mannheim to 31.4 in Chemnitz; Königsberg 30.4; Breslau 29.6; Munich 30.1; Dresden 29.7; Berlin 24.6; Leipzig 24; Hamburg 25.6; Cologne 25.5; Frankfurt a. M. 18.1; Strasburg 18.2.

The meteorological record for the week ending December 15th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps:—

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING DECEMBER 22, 1883.

DALY, F. C., passed assistant surgeon. Detached from the Coast Survey Steamer McArthur and ordered to the U. S. S. Adams at Sitka, Alaska.

CURTIS, L. W., assistant surgeon. Detached from the Adams and ordered to the Coast Survey Steamer McArthur.

ROSS, J. W., surgeon. Detached from the U. S. S. Iroquois and ordered to the U. S. S. Onward at Callao, Peru.

HIBBERT, C. T., passed assistant surgeon. Detached from the Onward and ordered home.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM DECEMBER 14, 1883, TO DECEMBER 21, 1883.

CAMPBELL, JOHN, lieutenant-colonel and surgeon. Having completed the duties pertaining to the office of the Medical Director of the late Department of the South, to proceed from Newport Barracks, Ky., to New York City, and assume the duties of attending surgeon in that city. Paragraph 12, S. O. 284, A. G. O., December 12, 1883.

CLEMENTS, BENNETT A., major and surgeon. Relieved from duty as attending surgeon New York City, and detailed as

member of Army Medical Examining Board, now in session in New York City. Paragraph 12, S. O. 284, A. G. O., December 12, 1883.

McKEE, J. C., major and surgeon. Assigned to duty as Medical Director Department of the Columbia. G. O. 31, Department of the Columbia, December 3, 1883.

WILLIAMS, JOHN W., major and surgeon. Leave of absence on surgeon's certificate of disability granted in S. O. 157, November 12, 1883, Department of the Columbia, extended five months on surgeon's certificate of disability. Paragraph 6, S. O. 286, A. G. O., December 14, 1883.

THE SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY will meet at 19 Boylston Place on Wednesday, January 2, 1884, at 7.45 P. M. Papers: A Case of Cysto-Pyelitis, or Pyelo-Cystitis, or Cystitis Coincident with Pyelitis, Dr. E. O. Otis. Abscesses of Abdominal Wall, Dr. W. Ingalls.

S. J. MIXTER, Secretary.
